

David G. Myers C. Nathan DeWall

PSYCHOLOGY

12th edition

The Story of Psychology: A Timeline

by Charles L. Brewer, Furman University

B.C.E.

- 387** — Plato, who believed in innate ideas, suggests that the brain is the seat of mental processes.
- 335** — Aristotle, who denied the existence of innate ideas, suggests that the heart is the seat of mental processes.

C.E.

- 1604** — Johannes Kepler describes inverted image on the retina.
- 1605** — Francis Bacon publishes *The Proficiency and Advancement of Learning*.
- 1636** — Harvard College is founded.
- 1637** — René Descartes, the French philosopher and mathematician who proposed mind-body interaction and the doctrine of innate ideas, publishes *A Discourse on Method*.
- 1690** — John Locke, the British philosopher who rejected Descartes' notion of innate ideas and insisted that the mind at birth is a "blank slate" (*tabula rasa*), publishes *An Essay*

- Concerning Human Understanding*, which stresses empiricism over speculation.
- 1774** — Franz Mesmer, an Austrian physician, performs his first supposed cure using “animal magnetism” (later called mesmerism and hypnosis). In 1777 he was expelled from the practice of medicine in Vienna.
- 1793** — Philippe Pinel releases the first mental patients from their chains at the Bicêtre Asylum in France and advocates for more humane treatment of mental patients.
- 1802** — Thomas Young publishes *A Theory of Color Vision* in England. (His theory was later called the trichromatic theory.)
- 1808** — Franz Joseph Gall, a German physician, describes phrenology, the belief that the shape of a person’s skull reveals mental faculties and character traits.
- 1813** — The first private psychiatric hospital in the United States opens in Philadelphia.
- 1834** — Ernst Heinrich Weber publishes *The Sense of Touch*, in which he discusses the “just noticeable difference (*jnd*)” and what we now call Weber’s law.

- 1844** — In Philadelphia, 13 superintendents form *The Association of Medical Superintendents of American Institutions for the Insane* (now known as the American Psychiatric Association).
- 1848** — Phineas Gage suffers massive brain damage when a large iron rod accidentally pierces his brain, leaving his intellect and memory intact but altering his personality.
- 1850** — Hermann von Helmholtz measures the speed of the nerve impulse.
- 1859** — Charles Darwin publishes *On the Origin of Species by Means of Natural Selection*, synthesizing much previous work on the theory of evolution, including that of Herbert Spencer, who coined the phrase “survival of the fittest.”
- 1861** — Paul Broca, a French physician, discovers an area in the left frontal lobe of the brain (now called Broca’s area) that is critical for the production of spoken language.
- 1869** — Francis Galton, Charles Darwin’s cousin, publishes *Hereditary Genius*, in which he claims that intelligence is inherited. In 1876 he coins the expression “nature and nurture” to correspond with “heredity and environment.”

- 1874** — Carl Wernicke, a German neurologist and psychiatrist, shows that damage to a specific area in the left temporal lobe (now called Wernicke's area) disrupts ability to comprehend or produce spoken or written language.
- 1878** — G. Stanley Hall receives from Harvard University's Department of Philosophy the first U.S. Ph.D. degree based on psychological research.
- 1879** — Wilhelm Wundt establishes at the University of Leipzig, Germany, the first psychology laboratory, which becomes a mecca for psychology students from all over the world.
- 1883** — G. Stanley Hall, student of Wilhelm Wundt, establishes the first formal U.S. psychology laboratory at Johns Hopkins University.
- 1885** — Hermann Ebbinghaus publishes *On Memory*, summarizing his extensive research on learning and memory, including the "forgetting curve."
- 1886** — Joseph Jastrow receives from Johns Hopkins University the first Ph.D. degree in psychology awarded by a Department of Psychology in the United States.
- 1889** — Alfred Binet and Henri Beaunis establish the first psychology

- laboratory in France at the Sorbonne, and the first International Congress of Psychology meets in Paris.
- 1890** — William James, Harvard University philosopher and psychologist, publishes *The Principles of Psychology*, describing psychology as “the science of mental life.”
- 1891** — James Mark Baldwin establishes the first psychology laboratory in the British Commonwealth at the University of Toronto.
- 1892** — G. Stanley Hall spearheads the founding of the American Psychological Association (APA) and becomes its first president.
- 1893** — Mary Whiton Calkins and Christine Ladd-Franklin are the first women elected to membership in the APA.
- 1894** — Margaret Floy Washburn is the first woman to receive a Ph.D. degree in psychology (Cornell University).
- Harvard University denies Mary Whiton Calkins admission to doctoral candidacy because of her gender, despite Hugo Münsterberg’s claim that she was the best student he had ever had there.
- 1896** — John Dewey publishes “The Reflex Arc Concept in Psychology,” helping to formalize the school of

- psychology called functionalism.
- 1898** — In *Animal Intelligence*, Edward L. Thorndike, Columbia University, describes his learning experiments with cats in “puzzle boxes.” In **1905**, he proposes the “law of effect.”
- 1900** — Sigmund Freud publishes *The Interpretation of Dreams*, his major theoretical work on psychoanalysis.
- 1901** — Ten founders establish the British Psychological Society.
- 1904** — Ivan Pavlov is awarded the Nobel Prize for Physiology or Medicine for his studies on the physiology of digestion.
- 1905** — Mary Whiton Calkins becomes the first woman president of the APA.
- Ivan Petrovich Pavlov begins publishing studies of conditioning in animals.
- Alfred Binet and Théodore Simon produce the first intelligence test for assessing the abilities and academic progress of Parisian schoolchildren.
- 1909** — Sigmund Freud makes his only trip to America to deliver a series of lectures at Clark University.
- 1913** — John B. Watson outlines the tenets of behaviorism in a *Psychological Review* article, “Psychology as the

- Behaviorist Views It.”
- 1914** — During World War I, Robert Yerkes and his staff develop a group intelligence test for evaluating U.S. military personnel, which increases the U.S. public’s acceptance of psychological testing.
- 1920** — Leta Stetter Hollingworth publishes *The Psychology of Subnormal Children*, an early classic. In **1921** she is cited in *American Men of Science* for her research on the - psychology of women.
- Francis Cecil Sumner receives a Ph.D. degree in psychology from Clark University, becoming the first African-American to earn a psychology doctorate.
- John B. Watson and Rosalie Rayner report conditioning a fear reaction in a child called “Little Albert.”
- 1921** — Hermann Rorschach, a Swiss psychiatrist, introduces the Rorschach Inkblot Test.
- 1923** — Developmental psychologist Jean Piaget publishes *The Language and Thought of the Child*.
- 1924** — Mary Cover Jones reports reconditioning a fear reaction in a child (Peter), a forerunner of systematic desensitization developed by Joseph Wolpe.

- 1927** — In *Introduction to the Technique of Child Analysis*, Anna Freud discusses psychoanalysis in the treatment of children.
- 1929** — Wolfgang Köhler publishes *Gestalt Psychology*, which criticizes behaviorism and outlines essential elements of the gestalt position and approach.
- 1931** — Margaret Floy Washburn becomes the first female psychologist (and the second female scientist in any discipline) elected to the U.S. National Academy of Sciences.
- 1932** — In *The Wisdom of the Body*, Walter B. Cannon coins the term *homeostasis*, discusses the fight-or-flight response, and identifies hormonal changes associated with stress.
- 1933** — Inez Beverly Prosser becomes the first African-American woman to receive a doctoral degree in psychology from a U.S. institution (Ph.D., University of Cincinnati).
- 1935** — Christiana Morgan and Henry Murray introduce the Thematic Apperception Test to elicit fantasies from people undergoing psychoanalysis.
- 1936** — Egas Moniz, a Portuguese physician,

- publishes work on the first frontal lobotomies performed on humans.
- 1938** — B. F. Skinner publishes *The Behavior of Organisms*, which describes operant conditioning of animals.
- In *Primary Mental Abilities*, Louis L. Thurstone proposes seven such abilities.
- Ugo Cerletti and Lucio Bini use electroshock treatment with a human patient.
- 1939** — David Wechsler publishes the Wechsler–Bellevue intelligence test, forerunner of the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Adult Intelligence Scale (WAIS).
- Mamie Phipps Clark receives a master’s degree from Howard University. In collaboration with Kenneth B. Clark, she later extends her thesis, “The Development of Consciousness of Self in Negro Preschool Children,” providing joint research cited in the U.S. Supreme Court’s **1954** decision to end racial segregation in public schools.
- Edward Alexander Bott helps found the Canadian Psychological Association. He becomes its first president in **1940**.

— World War II provides many opportunities for psychologists to enhance the popularity and influence of psychology, especially in applied areas.

1943 — Psychologist Starke Hathaway and physician J. Charnley McKinley publish the Minnesota Multiphasic Personality Inventory (MMPI).

1945 — Karen Horney, who criticized Freud's theory of female sexual development, publishes *Our Inner Conflicts*.

1946 — Benjamin Spock's first edition of *The Commonsense Book of Baby and Child Care* appears; the book will influence child raising in North America for several decades.

1948 — Alfred Kinsey and his colleagues publish *Sexual Behavior in the Human Male*, and they publish *Sexual Behavior in the Human Female* in **1953**.

— B. F. Skinner's novel, *Walden Two*, describes a Utopian community based on positive reinforcement, which becomes a clarion call for applying psychological principles in everyday living, especially communal living.

— Ernest R. Hilgard publishes *Theories*

- of Learning*, which was required reading for several generations of psychology students in North America.
- 1949** — Raymond B. Cattell publishes the Sixteen Personality Factor Questionnaire (16PF).
- The scientist-practitioner model of training is approved at The Boulder Conference on Graduate Education in Clinical Psychology.
- 1949** — In *The Organization of Behavior: A Neuropsychological Theory*, Canadian psychologist Donald O. Hebb outlines a new and influential conceptualization of how the nervous system functions.
- 1950** — Solomon Asch publishes studies of effects of conformity on judgments of line length.
- In *Childhood and Society*, Erik Erikson outlines his stages of psychosocial development.
- 1951** — Carl Rogers publishes *Client-Centered Therapy*.
- 1952** — The American Psychiatric Association publishes the *Diagnostic and Statistical Manual of Mental Disorders*, an influential book that will be updated periodically.

- 1953 — Eugene Aserinski and Nathaniel Kleitman describe rapid eye movements (REM) that occur during sleep.
- Janet Taylor's Manifest Anxiety Scale appears in the *Journal of Abnormal Psychology*.
- 1954 — In *Motivation and Personality*, Abraham Maslow proposes a hierarchy of motives ranging from physiological needs to self-actualization. (Maslow later updates the hierarchy to include self-transcendence needs.)
- James Olds and Peter Milner, McGill University neuropsychologists, describe the rewarding effects of electrical stimulation of the hypothalamus in rats.
- Gordon Allport publishes *The Nature of Prejudice*.
- 1956 — In his *Psychological Review* article titled "The Magical Number Seven, Plus or Minus Two: Some Limits on Our Capacity for Processing Information," George Miller coins the term *chunk* for memory researchers.
- 1957 — Robert Sears, Eleanor Maccoby, and Harry Levin publish *Patterns of Child Rearing*.

- Charles Ferster and B. F. Skinner publish *Schedules of Reinforcement*.
- 1958** — Harry Harlow outlines “The Nature of Love,” his work on attachment in monkeys.
- 1959** — Noam Chomsky’s critical review of B. F. Skinner’s *Verbal Behavior* appears in the journal *Language*.
- Eleanor Gibson and Richard Walk report their research on infants’ depth perception in “The Visual Cliff.”
- Lloyd Peterson and Margaret Peterson in the *Journal of Experimental Psychology* article, “Short-Term Retention of Individual Verbal Items,” highlight the importance of rehearsal in memory.
- John Thibaut and Harold Kelley publish *The Social Psychology of Groups*.
- 1960** — George Sperling publishes “The Information Available in Brief Visual Presentations.”
- 1961** — Georg von Békésy receives a Nobel Prize for research on the physiology of hearing.
- David McClelland publishes *The Achieving Society*.

- 1962** — Jerome Kagan and Howard Moss publish *Birth to Maturity*.
- Stanley Schachter and Jerome Singer publish findings that support the two-factor theory of emotion.
- Albert Ellis' *Reason and Emotion in Psychotherapy* appears; it is a milestone in the development of rational-emotive therapy (RET).
- 1963** — Raymond B. Cattell distinguishes between *fluid* and *crystallized* intelligence.
- Stanley Milgram's "Behavioral Study of Obedience" appears in the *Journal of Abnormal and Social Psychology*.
- 1965** — Canadian researcher Ronald Melzack and British researcher Patrick Wall propose the gate-control theory of pain.
- Robert Zajonc's "Social Facilitation" is published in *Science*.
- The Archives of the History of American Psychology is founded at the University of Akron.
- 1966** — Nancy Bayley becomes the first woman to receive the APA's Distinguished Scientific Contribution Award.
- Jerome Bruner and colleagues at

- Harvard University's Center for Cognitive Studies publish *Studies in Cognitive Growth*.
- William Masters and Virginia Johnson publish results of their research in *Human Sexual Responses*.
- Allen Gardner and Beatrix Gardner begin training a chimpanzee (Washoe) in American Sign Language at the University of Nevada, Reno. Washoe dies in 2007.
- John Garcia and Robert Koelling publish a study on taste aversion in rats.
- David M. Green and John A. Swets publish *Signal Detection Theory and Psychophysics*.
- Julian Rotter publishes research on locus of control.
- 1967** — Ulric Neisser's *Cognitive Psychology* helps to steer psychology away from behaviorism and toward cognitive processes.
- Martin Seligman and Steven Maier publish the results of their research with "learned helplessness" in dogs.
- 1968** — Richard Atkinson and Richard Shiffrin's influential three-stage memory model appears in *The Psychology of Learning and*

Motivation.

- Neal E. Miller's article in *Science*, describing instrumental conditioning of autonomic responses, stimulates research on biofeedback.

1969 — Albert Bandura publishes *Principles of Behavior Modification*.

- In his APA presidential address, "Psychology as a Means of Promoting Human Welfare," George Miller emphasizes the importance of "giving psychology away."

1971 — Kenneth B. Clark becomes the first African-American president of the American Psychological Association.

- Albert Bandura publishes *Social Learning Theory*.

- Allan Paivio publishes *Imagery and Verbal Processes*.

- B. F. Skinner publishes *Beyond Freedom and Dignity*.

1972 — Elliot Aronson publishes *The Social Animal*.

- Fergus Craik and Robert Lockhart's "Levels of Processing: A Framework for Memory Research" appears in the *Journal of Verbal Learning and Verbal Behavior*.

- Robert Rescorla and Allan Wagner publish their associative model of Pavlovian conditioning.
- Under the leadership of Derald Sue and Stanley Sue, the Asian American Psychological Association is founded.
- 1973** — Ethologists Karl von Frisch, Konrad Lorenz, and Nikolaas Tinbergen receive the Nobel Prize for their research on animal behavior.
- 1974** — APA's Division 2 first publishes its journal, *Teaching of Psychology*, with Robert S. Daniel as editor.
- Eleanor Maccoby and Carol Jacklin publish *The Psychology of Sex Differences*.
- 1975** — Biologist Edward O. Wilson's *Sociobiology* appears; it will be a controversial precursor to evolutionary psychology.
- 1976** — Sandra Wood Scarr and Richard A. Weinberg publish "IQ Test Performance of Black Children Adopted by White Families" in *American Psychologist*.
- Psychologist Robert V. Guthrie publishes *Even the Rat Was White*, the first history of African-American psychologists in America.
- 1978** — Psychologist Herbert A. Simon,

- Carnegie-Mellon University, wins a Nobel Prize for pioneering research on computer simulations of human thinking and problem solving.
- 1979** — James J. Gibson publishes *The Ecological Approach to Visual Perception*.
- Elizabeth Loftus publishes *Eyewitness Testimony*.
- 1981** — David Hubel and Torsten Wiesel receive a Nobel Prize for research on single-cell recordings that identified feature detector cells in the visual cortex.
- Roger Sperry receives a Nobel Prize for research on split-brain patients.
- Paleontologist Stephen Jay Gould publishes *The Mismeasure of Man*, highlighting the debate concerning biological determination of intelligence.
- 1983** — In his *Frames of Mind*, Howard Gardner outlines his theory of multiple intelligences.
- 1984** — The American Psychological Association creates Division 44 (Society for the Psychological Study of Lesbian and Gay Issues).
- Robert Sternberg proposes the triarchic theory of human intelligence in *Behavioral and Brain*

Sciences.

1987 — Elizabeth Scarborough and Laurel Furumoto publish *Untold Lives: The First Generation of American Women Psychologists*.

— Fluoxetine (Prozac) is introduced as a treatment for depression.

— Wilbert J. McKeachie, University of Michigan, receives the first APA Award for Distinguished Career Contributions to Education and Training in Psychology.

1988 — The American Psychological Society is founded. It changes its name to Association for Psychological Science in 2006.

1990 — Psychiatrist Aaron Beck receives the Distinguished Scientific Award for the Applications of Psychology for advancing understanding and treatment of psychopathology, including pivotal contributions to the development of cognitive therapy.

— B. F. Skinner receives APA's first Citation for Outstanding Lifetime Contributions to Psychology and presents his last public address, "Can Psychology Be a Science of Mind?" (He died a few days later at age 86.)

1991 — Martin Seligman publishes *Learned*

- Optimism*, which foreshadows the “positive psychology” movement.
- 1992** — Teachers of Psychology in Secondary Schools (TOPSS) is established as part of the APA.
- About 3,000 U.S. secondary school students take the first Advanced Placement (AP) Examination in Psychology, hoping to earn exemption from an introductory psychology course at the postsecondary level.
- 1993** — Psychologist Judith Rodin is elected president of the University of Pennsylvania, becoming the first female president of an Ivy League school.
- 1996** — Dorothy Cantor becomes the first president of the APA with a Psy.D. degree.
- 2002** — New Mexico becomes the first U.S. state to allow qualified clinical psychologists to prescribe certain drugs.
- Psychologist Daniel Kahneman, Princeton University, receives a Nobel Prize for research on decision making.
- Proposed by participants at the 2008 national conference at the University of Puget Sound, the document,

“Principles for Quality Undergraduate Education in Psychology,” is approved as official APA policy.

2013 — U.S. President Barack Obama announces \$100 million in funding for an interdisciplinary project to advance understanding of the human brain.

2015 — The *Independent Review Relating to APA Ethics Guidelines, National Security Interrogations, and Torture* is presented to the American Psychological Association.

About the Authors

Hope College
Public Relations

David Myers received his B.A. in chemistry from Whitworth University, and his psychology Ph.D. from the University of Iowa. He has spent his career at Hope College in Michigan, where he has taught dozens of introductory psychology sections. Hope College students have invited him to be their commencement speaker and voted him “outstanding professor.”

His research and writings have been recognized by numerous awards and honors, including the Gordon Allport Intergroup Relations Prize, an Honored Scientist award from the Federation of Associations in Behavioral & Brain Sciences, an Award for Service on Behalf of Personality and Social Psychology, a Presidential Citation from APA Division 2, election as an American Association for the Advancement of Science Fellow, and three honorary doctorates.

With support from National Science Foundation grants, Myers’ scientific articles have appeared in three dozen scientific periodicals, including *Science*, *American Scientist*, *Psychological Science*, and the *American Psychologist*. In addition to his scholarly and textbook writing, he digests psychological science for the general public. His writings have appeared in four dozen magazines, from *Today’s Education* to *Scientific American*. He also has authored five general audience books, including *The Pursuit of Happiness* and *Intuition: Its Powers and Perils*.

David Myers has chaired his city’s Human Relations Commission, helped

found a thriving assistance center for families in poverty, and spoken to hundreds of college, community, and professional groups worldwide.

Drawing on his experience, he also has written articles and a book (*A Quiet World*) about hearing loss, and he is advocating a transformation in American assistive listening technology (see HearingLoop.org). For his leadership, he has received awards from the American Academy of Audiology, the hearing industry, and the Hearing Loss Association of America.

David and Carol Myers met and married while undergraduates, and have raised sons Peter and Andrew, and a daughter, Laura. They have one grandchild, Allie (seen on [page 165](#)).

J.A. Laub Photography, LLC

Nathan DeWall is professor of psychology and director of the Social Psychology Lab at the University of Kentucky. He received his bachelor's degree from St. Olaf College, a master's degree in social science from the University of Chicago, and a master's degree and Ph.D. in social psychology from Florida State University. DeWall received the College of Arts and Sciences Outstanding Teaching Award, which recognizes excellence in undergraduate and graduate teaching. The Association for Psychological Science identified DeWall as a "Rising Star" early in his career for "making significant contributions to the field of psychological science."

DeWall conducts research on close relationships, self-control, and aggression. With funding from the National Institutes of Health and the National Science Foundation, he has published over 190 scientific articles and chapters. DeWall's research awards include the SAGE Young Scholars Award from the Foundation for Personality and Social Psychology, the

Young Investigator Award from the International Society for Research on Aggression, and the Early Career Award from the International Society for Self and Identity. His research has been covered by numerous media outlets, including Good Morning America, *The Wall Street Journal*, *Newsweek*, *The Atlantic Monthly*, *The New York Times*, *The Los Angeles Times*, *Harvard Business Review*, *USA Today*, National Public Radio, the BBC, and *The Guardian*. He has lectured nationally and internationally, including in Hong Kong, China, the Netherlands, England, Greece, Hungary, Sweden, and Australia.

Nathan is happily married to Alice DeWall and is the proud father of Beverly “Bevy” and Ellis. He enjoys playing with his two golden retrievers, Finnegan and Atticus. In his spare time, he writes novels, watches sports, tends his chickens and goats, and runs and runs and runs. He has braved all climates—from the snowy trails of Michigan to the scorching sands of the Sahara Desert—to complete over 1000 miles’ worth of ultramarathons—including the Badwater 135 in 2017 (dubbed “the World’s toughest foot race”).

[Biology, Cognition, and Learning](#)

[Biological Constraints on Conditioning](#)

[Cognition's Influence on Conditioning](#)

[Learning by Observation](#)

[THINKING CRITICALLY ABOUT: The Effects of Viewing Media Violence](#)

[CHAPTER 8](#)

Memory

Studying and Encoding Memories

Studying Memory

Encoding Memories

Storing and Retrieving Memories

Memory Storage

Memory Retrieval

Forgetting, Memory Construction, and Improving Memory

Forgetting

Memory Construction Errors

THINKING CRITICALLY ABOUT: Can Memories of Childhood

Sexual Abuse Be Repressed and Then Recovered?

Improving Memory

CHAPTER 9

Thinking and Language

Thinking

Concepts

Problem Solving: Strategies and Obstacles

Forming Good (and Bad) Decisions and Judgments

THINKING CRITICALLY ABOUT: The Fear Factor

Thinking Creatively

Do Other Species Share Our Cognitive Skills?

Language and Thought

Language Structure

Language Acquisition and Development

The Brain and Language

Do Other Species Have Language?

Thinking and Language

CHAPTER 10

Intelligence

What Is Intelligence?

Is Intelligence One General Ability?

Theories of Multiple Intelligences

Emotional Intelligence

Assessing Intelligence

Early and Modern Tests of Mental Abilities

Principles of Test Construction

The Dynamics of Intelligence

Stability or Change?

THINKING CRITICALLY ABOUT: Cross-Sectional and Longitudinal Studies

Extremes of Intelligence

Genetic and Environmental Influences on Intelligence

Twin and Adoption Studies

Environmental Influences

Group Differences in Intelligence Test Scores

CHAPTER 11

What Drives Us: Hunger, Sex, Belonging, and Achievement

Basic Motivational Concepts

Instincts and Evolutionary Theory

Drives and Incentives

Arousal Theory

A Hierarchy of Needs

Hunger

The Physiology of Hunger

The Psychology of Hunger

THINKING CRITICALLY ABOUT: The Challenges of Obesity and Weight Control

Sexual Motivation

The Physiology of Sex

The Psychology of Sex

Sexual Orientation

Sex and Human Relationships

Affiliation and Achievement

The Need to Belong

Achievement Motivation

CHAPTER 12

Emotions, Stress, and Health

Introduction to Emotion

Emotion: Arousal, Behavior, and Cognition

Embodied Emotion

THINKING CRITICALLY ABOUT: Lie Detection

Expressing Emotion

Detecting Emotion in Others

Gender, Emotion, and Nonverbal Behavior

Culture and Emotional Expression

The Effects of Facial Expressions

Experiencing Emotion

Anger

Happiness

Instructor Preface:

Not All Psychology Resources Are Alike

Psychology is fascinating, and so relevant to our everyday lives. Psychology's insights enable students to be more successful in their courses, more tuned-in as friends and partners, more effective as co-workers, and wiser as parents. With this new edition, we hope to captivate students with what psychologists are learning about our human nature, and to help them think more like psychological scientists and appreciate the wonders of their own lives. Psychological science has the potential to expand their minds and enlarge their hearts—to supplement their intuition with critical thinking, restrain their judgmentalism with compassion, and replace their illusions with understanding.

Just as introductory psychology *teachers* differ, introductory psychology *resources* differ. They vary in quality, effectiveness, and ease of use. With help from Worth Publishers, we've heard from hundreds of psychology instructors like you who have told us about their needs and concerns, and about the challenges faced by their students. Here are ten frequently mentioned issues, and how we've responded with this *Psychology*, Twelfth Edition text and resources.

1 “I would like my students to come to class better prepared.”

Our Resources Are Carefully Designed to Help Students Learn, and Care About Their Learning

We and our team work hard to create top-quality resource materials. To encourage students to read assigned material, we aim to communicate psychology's story with crisp writing, vivid storytelling, and occasional humor. After gathering input from many hundreds of instructors and their

students over the years—much of it unsolicited—I [DM] have learned much about how to engage students effectively. My co-author, Nathan DeWall (an award-winning teacher from the University of Kentucky) and I communicate often about how best to reach students so they can share our fascination, and ultimately find success in the course (and in their lives).

We get help from our team of editors, who work with us line-by-line on the text manuscript, and screen-by-screen for online activities. Equal care and attention are given to the text's Instructor's Resources and assessment materials. Our text chapters for this new edition went through six to seven drafts, and all other resources also went through multiple drafts. This creative process is intense and requires our daily focus. From the moment we wake to when we sleep, we collect, critique, and create new information that will expand students' minds and hearts. Working through what is often over *one thousand* edits and comments in a given chapter can be daunting! But we think it's worth it in the end to give students the best possible chance at success in this life-relevant course. With the support of Worth Publishers, our author and editorial team has no rival in its investment of time and energy to maximize excellence for optimal student enjoyment and enrichment.

Students Love This Book

Students seem to appreciate the effort. They read the book! We get a stream of wonderfully encouraging, and sometimes funny, letters from appreciative students. (See the back cover of this text for a few more examples.)

“Mr. Myers: I have been reading . . . your Psychology textbook. . . . The way you write and explain makes me feel like we're buddies.”

—FROM AN ANONYMOUS STUDENT

“Your text goes above and beyond; your command of language, the . . . witty remarks and puns, the frequent inclusion of concrete psychological experiments pertaining to the . . . subject. I often found myself nodding my head while reading along, as I felt like the information I was taking in was substantiated with real life applications.”

—FROM SABRINA HALAVI, SANTA MONICA COLLEGE

Students also love the online learning resources. We hear repeatedly that students benefit from the LearningCurve formative quizzing system and use

it both to explore new concepts and to test their understanding.

Sabrina Halavi

2 “I need especially reliable, current, excellent materials, because this is an introductory course.”

At the introductory level, high quality, cohesive, connected materials—text, assessment, review—are essential for students’ success.

Psychology, Twelfth Edition Contains Over 1100 New Research Citations

The work of creating our text and online resources begins as Nathan and I stay current with new psychological research. We scrutinize dozens of scientific periodicals and science news sources. Worth Publishers commissions numerous reviews, and we receive countless e-mails from instructors and students. These sources feed our reporting on psychology’s most important, thought-provoking, and student-relevant new discoveries. Part of the pleasure that sustains this work is learning something new every day! Each new edition is an adventure down the ever-changing road of psychological science. Every topic is inspected closely and painstakingly updated. This time around, it’s been particularly fun to watch all of the developments in neuroscience ([TABLE 1](#)) and in behavior genetics ([TABLE](#)

2). The end result is well over 1100 new citations for this edition. See MacmillanLearning.com for our lengthy, chapter-by-chapter list of significant **Content Changes**.

Behavior Genetics and Evolutionary Psychology

In addition to the coverage found in Chapter 4 , behavior genetics is covered on the following pages:			
Abuse, intergenerational transmission of, p. 292 Adaptability, p. 74 Aggression, pp. 504–505 intergenerational transmission of, p. 292 Autism spectrum disorder, pp. 180–182 Behavior genetics perspective, pp. 10–11 Biological perspective, pp. 50–51 Brain plasticity, pp. 51–52 Continuity and stages, p. 167 Deprivation of attachment, pp. 187–188 Depth perception, pp.	Drug use and dependence, pp. 122–123 Eating disorders, pp. 605–606 Epigenetics, pp. 135–136, 170, 564, 578, 587 Happiness, pp. 444–448 Hunger and taste preference, pp. 398–399 Intelligence: Down syndrome, p. 376 genetic and environmental influences, pp. 377–378 Learning, pp. 284–286 Motor development, p. 173 Nature–nurture, pp.	Pain, pp. 247–251 Parenting styles, pp. 145–146, 189–190 Perception, pp. 239–240 Personality traits, pp. 543–546 Psychological disorders and: ADHD, p. 567 anxiety disorders, p. 573 biopsychosocial approach, pp. 564–565 bipolar disorder and depressive disorders, pp. 585–587 depression, pp. 581, 585–587 obsessive-compulsive disorder, p. 575 personality	schizophrenia, pp. 596–598 suicide, pp. 590–592 violent behavior, p. 569 Reward deficiency syndrome, p. 71 Romantic love, p. 208 Sexual dysfunction, p. 405 Sexual orientation, pp. 412–414 Sexuality, pp. 402–404 Sleep patterns, pp. 100–101 Smell, pp. 252–253 Stress, personality, and illness, pp. 459–461 benefits of exercise, pp. 469–471

234–235	10–11	disorders, pp. 602–604	Traits, pp. 366–367 380–381
Development, pp. 169–170	twins, p. 11	posttraumatic stress disorder, pp. 576–579	gay-straight tra differences, pp. 414–415
Drives and incentives, p. 391	Obesity and weight control, p. 401		See also Chapter 2 The Biology of Behavior.
	Optimism, pp. 466–467		
In addition to the coverage found in Chapter 4, the evolutionary perspective covered on the following pages:			
Aging, p. 203	Depression and light exposure therapy, p. 630	Hearing, p. 242	Overconfidence, p. 336
Anger, pp. 441–443	Emotion, effects of facial expressions and, p. 439	Hunger and taste preferences, pp. 398–399	Perceptual adaptation, pp. 239–240
Anxiety disorders, p. 579	Emotional expression, p. 437	Instincts, pp. 390–391	Puberty, onset of, p. 157–158 , 192
Biological predispositions:	Evolutionary perspective, defined, pp. 12–13	Intelligence, pp. 365–366 , 382–384	Sensation, p. 215
in learning, pp. 283–288	Exercise, p. 469	Language, pp. 334 , 346–350	Sensory adaptation, pp. 218–219
in operant conditioning, pp. 285–288	Fear, p. 335	Love, p. 208	Sexual orientation, pp. 412–413
Brainstem, pp. 68–70	Feature detection, pp. 230–231	Math and spatial ability, p. 382	Sexuality, pp. 139–142 , 402
Classical conditioning, pp. 283–285	Fight or flight, pp. 454–455	Mating preferences, pp. 141–142	Sleep, p. 101
Consciousness, pp. 88–89	Gene-environment interaction, pp. 135–136	Menopause, p. 202	Smell, pp. 252–253
Darwin, Charles, pp. 10 , 137–139		Need to belong, pp. 417–418	Taste, p. 251
		Obesity, p. 401	See also Chapter 2 The Biology of Behavior.

Eight Principles Have Always Guided This Text's Creation

Nathan and I follow eight guiding principles that have animated all of my texts since their first editions.

Facilitating the Learning Experience

- . **To teach critical thinking** By presenting research as intellectual detective work, we illustrate an inquiring, analytical mindset. Whether students are studying development, cognition, or social behavior, they will be drawn into critical reasoning. They will discover how an empirical approach can help them evaluate competing ideas and claims for highly publicized phenomena—ranging from extrasensory perception and alternative therapies to group differences in intelligence and repressed and recovered memories. Our new “Thinking Critically About” infographic features help engage students in this learning.
- . **To integrate principles and applications** Throughout, we relate the findings of basic research to their applications and implications. Knowledge is power when we harness it to bring about positive change in the world. Where psychology can illuminate pressing human issues—overcoming prejudice, pursuing happiness, moving past conflict to peace—we have not hesitated to shine its light. Our online “Assess Your Strengths” activities invite students to apply important concepts to their own lives, and to learn ways to develop personal strengths. As the author of an early book devoted to the scientific study of happiness, *The Pursuit of Happiness* (Myers, 1993), I [DM] have a special place in my heart for understanding and cultivating human strengths. Throughout the text we integrate coverage of *positive psychology* (see [TABLE 3](#)).
- . **To reinforce learning at every step** Everyday examples and thought-provoking questions encourage students to process the material actively. Concepts presented earlier are frequently applied, and reinforced, in later chapters. For instance, in [Chapter 1](#), students learn that much of our information processing occurs outside of our conscious awareness. Subsequent chapters drive home this concept. Self-testing opportunities throughout the text and online resources help students learn and retain important concepts and terminology.

TABLE 3
Examples of Positive Psychology

Coverage of positive psychology topics can be found in the following Chapters:
--

Topic	Chapter
Altruism/compassion	7 , 9 , 12 , 13
Coping	12
Courage	13
Creativity	9 , 10
Emotional intelligence	10
Empathy	6 , 7 , 12 , 14 , 16
Flow	12 , Appendix A
Gratitude	12
Happiness/Life satisfaction	Prologue , 5 , 11 , 12 , 13 , 14
Humility	Prologue
Humor	12
Leadership	4 , 14 , Appendix A
Love	4 , 5 , 11 , 12 , 13 ,
Morality	5
Optimism	12 , 14
Personal control	12
Resilience	5 , 12 , 16
Self-awareness	5 , 14 , 16
Self-discipline	5 , 10 , 11 , 12
Self-efficacy	14 , 16
Self-esteem	11 , 12 , 14
Spirituality	5 , 12
Toughness (grit)	10 , 11
Wisdom	9 , 10 , 14

Demonstrating the Science of Psychology

. ***To teach the process of inquiry*** We strive to show students not just the outcome of research, but how the research process works. Throughout, the narrative excites the reader’s curiosity. It invites students to imagine themselves as participants in classic experiments. Several chapters introduce research stories as mysteries that progressively unravel as one clue after another falls into place. Our online “Immersive Learning: How Would You Know?” activities encourage students to think about research questions and

how psychological scientists attempt to answer them.

- . ***To be as up-to-date as possible*** Few things dampen students' interest as quickly as the sense that they are reading stale news. While keeping psychology's classic studies and concepts, we also present the discipline's most important recent developments. In this edition, 1029 references are dated 2014–2017. Likewise, new photos and new everyday examples are drawn from today's world.
- . ***To put facts in the service of concepts*** Our intention is not to fill students' intellectual file drawers with facts, but to reveal psychology's major concepts—to teach students how to think, and to offer psychological ideas worth thinking about. While writing, we keep in mind a simple question: *What does an educated person need to know?* Learning Objective Questions and Retrieval Practice questions throughout each chapter help students focus on the most important concepts. Online Concept Practice activities help ensure student understanding of key points.

Promoting Big Ideas and Broadened Horizons

- . ***To enhance comprehension by providing continuity*** Many chapters have a significant issue or theme that links subtopics, forming a thread that ties the chapter together. The Learning chapter conveys the idea that bold thinkers can serve as intellectual pioneers. The Thinking and Language chapter raises the issue of human rationality and irrationality. The Psychological Disorders chapter conveys empathy for, and understanding of, troubled lives. Other threads, such as cognitive neuroscience, dual processing, and cultural, gender, and gender-identity diversity weave throughout the whole book. Although Nathan and I occupy separate bodies, we write with a unified voice. (We also have a similar sense of humor.) Our singleness of purpose and our editing of each other give students a familiar companion that will help guide them through psychology's interconnected roads.
- . ***To convey respect for human unity and diversity*** Throughout the book, readers will see evidence of our human kinship—our shared biological heritage, our common mechanisms of seeing and learning, hungering and feeling, loving and hating. They will also better understand the dimensions of our diversity—our individual diversity in development and aptitudes, temperament and personality, and disorder and health; and our cultural

diversity in attitudes and expressive styles, child raising and care for the elderly, and life priorities.

3 “Active learning is essential—I need materials that will help me engage students.”

Our Materials Engage Students With Active Learning

We’ve found that engaged students who are learning actively tend to be successful students. They do better in the course and are more likely to stay in school. It has been a joy for me [ND] to teach introductory psychology with this book and its resources. The online materials make it easy to engage students effectively starting on Day 1 of the class when I make a LaunchPad assignment. With immediate engagement, and active learning throughout the course, most students become hooked on psychology and stay in my class. This book and its resources help me not only to *engage* students, but also to *retain* them.

LaunchPad (LaunchPadWorks.com) facilitates active learning as it solves key challenges (see **FIGURE 1**). In combination with the meticulously created text, these online resources give students everything they need to prepare for class and exams, while giving you, as the instructor, everything *you* need to quickly set up a course, shape the content to your syllabus, craft presentations and lectures, assign and assess homework, and guide the progress of individual students and the class as a whole.

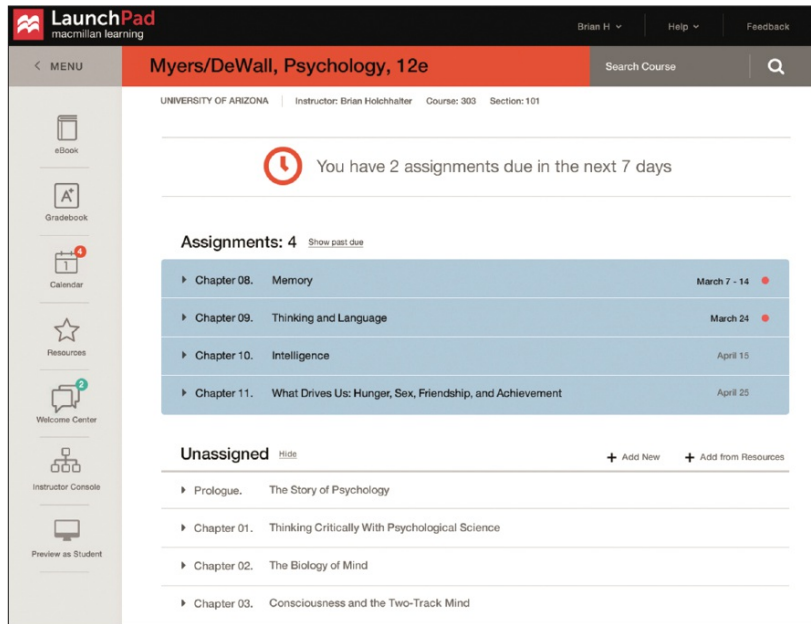

FIGURE 1 Sample from LaunchPad

- Our **NEW e-book** can now go with any student, anywhere. It is fully mobile-compatible and meets accessibility standards.
- **LearningCurve's game-like quizzing** motivates students and adapts to their needs based on their performance. It is the perfect tool to get students to engage before class, and review after. Additional reporting tools and metrics will help you assess the progress of individual students and the class as a whole.

- **iClicker offers active learning simplified, and now includes the REEF mobile app (iClicker.com)**. iClicker's simple, flexible tools in LaunchPad help you give students a voice and facilitate active learning in the classroom. Students can use iClicker remotes, or the REEF mobile app on their phone, tablet, or laptop to participate more meaningfully.
- **The NEW Concept Practice collection** offers 120 dynamic, interactive mini-tutorials that teach and reinforce the course's foundational ideas. Each brief activity (only five minutes to complete) addresses one or two concepts, in a consistent format—review, practice, quiz, and conclusion.
- The **PsychSim 6** tutorials, Thomas Ludwig's (Hope College) award-

winning interactive psychology simulations, were designed for the mobile web. PsychSim immerses students in the world of psychological research, placing them in the role of scientist or subject in activities that highlight important concepts, processes, and experimental approaches.

- In the revised **Assess Your Strengths** activities, students apply what they are learning from the text to their own lives and experiences by considering key “strengths.” Each activity starts with a personalized video introduction from us [DM and ND], explaining how that strength ties in to the content of the chapter. Next, students assess themselves on the strength (critical thinking, quality of sleep, self-control, relationship strength, belonging, hope, and more) using scales developed by researchers across psychological science. After showing students their results, we offer tips for nurturing that strength in students’ own lives. Finally, students take a quiz to help solidify their learning.
- **LMS integration** into your school’s system is readily available. Check with your local sales representative for details.
- **The Video Assignment Tool** makes it easy to assign and assess video-based activities and projects, and provides a convenient way for students to submit video coursework.
- The **Gradebook** gives a clear window on performance for the whole class, for individual students, and for individual assignments.
- A **streamlined interface** helps students manage their schedule of assignments, while **social commenting tools** let them connect with classmates, and learn from one another. 24/7 help is a click away, accessible from a link in the upper right-hand corner.
- We [DM and ND] curated **optional pre-built chapter units**, which can be used as is or customized. Or choose not to use them and build your course from scratch.
- **Instructor resources** include PowerPoint sets, textbook graphics, lecture and classroom activity suggestions (including many that work well for think-pair-share activities), Lecture Guides (summarizing key text discussions and connecting instructor resources with text learning objectives), and test banks.

Scattered throughout this book, students will also find interesting and informative notes and quotes from researchers and others that

will encourage them to be active learners and to apply their new knowledge to everyday life.

For this new edition, you will see that we've offered callouts from the text pages to especially pertinent, helpful online resources. (See [FIGURE 2](#) for a sample.)

 For an animated explanation of this process, engage online with **Concept Practice: Action Potentials**.

FIGURE 2 Sample callout to online resources from [Chapter 2](#)

The Macmillan Community Will Engage You, Too!

The **Macmillan Community** (Community.Macmillan.com) was created by instructors *for* instructors. This is an ideal forum for interacting with fellow educators—including Macmillan authors ([FIGURE 3](#)). Join ongoing conversations about everything from course prep and presentations to assignments and assessments, to teaching with media, keeping pace with—and influencing—new directions in your field. The Community offers exclusive access to classroom resources, blogs (including my [DM's] TalkPsych), webinars, and professional development opportunities. Our mission is to provide the highest quality educational resources to instructors and students. By participating in the Macmillan Community, you will join a group of enthusiastic educators who have unmatched access to high-quality resources and a forum to further your understanding of how to implement them.

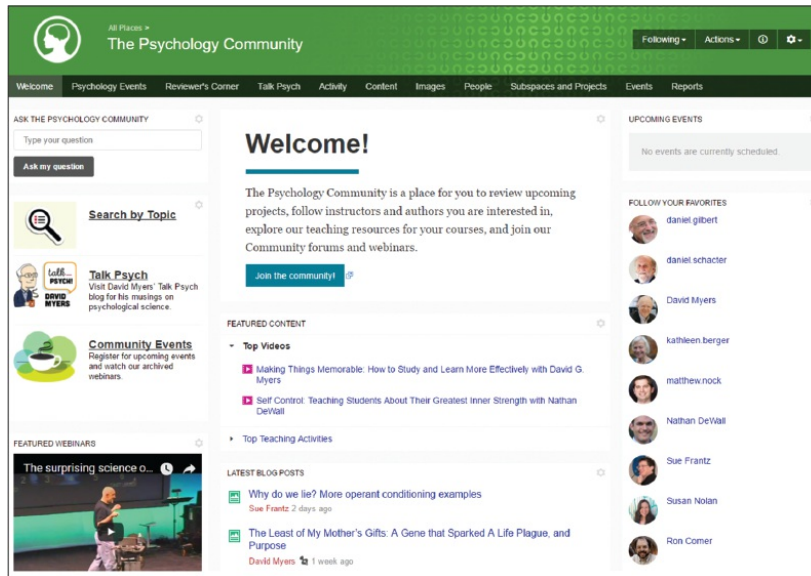

FIGURE 3 Sample from Macmillan Community
Community.Macmillan.com

4 “My students need truly effective learning tools they will use.”

Our Pedagogy Follows Best Practices From Learning and Memory Research

Students want to do well in this course, and we all want to give them the best possible chance of doing so. How can we best enhance student success? Use findings from psychological science to teach psychological science.

Researchers have found that “Achievement is . . . strongly associated with the stimulation of meaningful learning by presenting information in a clear way, relating it to the students, and using conceptually demanding learning tasks” (Schneider & Preckel, 2017). So, for starters, we write and rewrite our materials under scrutiny from each other and our team of editors—ensuring that each sentence is clear and compelling, and that our student readers will readily relate psychology’s concepts to their lives.

Our learning system also harnesses the *testing effect*, which documents the benefits of actively retrieving information through regular testing with *immediate feedback* (FIGURE 4). Thus, our LearningCurve system, which has been very popular with students, offers an adaptive quizzing program that provides a personalized study plan. In the text, each chapter offers 12 to 15 **Retrieval Practice** questions interspersed throughout (FIGURE 5). Creating these *desirable difficulties* for students along the way optimizes the testing effect, as does immediate feedback via answers that are available for checking.

FIGURE 4 How to learn and remember For a 5-minute animated guide to more effective studying, visit tinyurl.com/HowToRemember.

FIGURE 5 Sample of Retrieval Practice feature

Each main section of text begins with a numbered question that establishes a **learning objective** and directs student reading. The Review found at the end of each main section repeats these questions as a further self-testing opportunity (with answers in the Complete Chapter Reviews appendix). The Review section also offers a page-referenced list of **Terms and Concepts to Remember**, and **Master the Material** questions in multiple formats to promote optimal retention.

These features enhance the Survey-Question-Read-Retrieve-Review (SQ3R) format. Chapter outlines allow students to *survey* what's to come. Main sections begin with a learning objective *question* that encourages

students to *read* actively. Periodic Retrieval Practice sections and the section Review (with repeated Learning Objective Questions, Key Terms list, and Master the Material questions) encourage students to test themselves by *retrieving* what they know and *reviewing* what they don't. (See [Figure 5](#) for a Retrieval Practice sample.)

key terms Students will also find complete definitions of each important term in a page corner near the term's introduction in the narrative.

5 “My administrators are eager to see results—better learning outcomes and improved retention of students.”

Our Online Resources May Improve Retention of Students

When I [ND] taught introductory psychology recently, I asked my students at the end of the course what they liked best about the class. Most answered “LaunchPad!” I’ve enjoyed using these resources in my classes, because they allow me to engage my students so successfully. In fact, at my institution (University of Kentucky), I’ve been involved in efforts to improve retention of students. In my own class, I have found that assigning something in LaunchPad on the first day of class, and heavily relying on LaunchPad throughout the term, seems to improve retention in my large (~350-student) classes.

Researchers have begun to do efficacy studies with our online materials, and initial results have been promising. Our Learning Science Team, led by Dr. Adam Black (an award-winning researcher and digital innovation specialist), has several exciting projects underway. Stay tuned as we continue

to learn more (and let us know if you'd like to participate).

Our Resources Help Address APA Learning Goals and Outcomes

In 2011, the American Psychological Association (APA) approved the new **Principles for Quality Undergraduate Education in Psychology**. These broad-based principles and their associated recommendations are a guide to producing “psychologically literate citizens who apply the principles of psychological science at work and at home.” (See apa.org/education/undergrad/principles.aspx.)

APA's more specific **2013 Learning Goals and Outcomes**, from their *Guidelines for the Undergraduate Psychology Major*, Version 2.0, were designed to gauge progress in students graduating with psychology majors. (See apa.org/ed/precollege/about/psymajor-guidelines.pdf.) Many psychology departments use these goals and outcomes to help establish their own benchmarks for departmental assessment purposes. **TABLE 4** outlines the way *Psychology*, Twelfth Edition can help you and your department address the APA's Learning Goals and Outcomes.

6 “It’s very important that I teach my students to think critically, and build their scientific literacy skills.”

Teaching Critical Thinking Is the Foundation of These Resources

We love to write in a way that gets students thinking and keeps their minds active. Students will see how psychological science can help them evaluate competing ideas and highly publicized claims ranging from intuition, subliminal persuasion, and ESP to left-brained/right-brained, alternative therapies, and repressed and recovered memories. We help students build the scientific literacy skills they will need to separate intuitive fiction from empirical fact.

In *Psychology*, Twelfth Edition and its resources, students have many opportunities to learn or practice their critical thinking skills:

- ***[Chapter 1](#) takes a critical thinking approach to introducing students to psychology’s research methods.*** Understanding the weak points of our everyday thinking and common sense helps students see the need for psychological science. Critical thinking is introduced as a key term on page 3.
- ***“Thinking Critically About . . .” infographics*** are found in each chapter. In class testing, students have applauded this visual tool for thinking critically about key psychological concepts (parenting styles, gender bias, group polarization, introversion, lifestyle changes, and more). See [FIGURE 6](#) for an example.
- ***Detective-style stories*** throughout the text get students thinking critically about psychology’s key research questions. In [Chapter 9](#), for example, we present as a puzzle the history of discoveries about where and how language happens in the brain. We guide students through the puzzle, showing them how researchers put all the pieces together.
- ***“Try this” and “think about it”*** style discussions and side notes engage students. We often encourage students to imagine themselves as participants in experiments. In [Chapter 13](#), for example, students take the perspective of participants in a Solomon Asch conformity experiment and, later, in one of Stanley Milgram’s obedience experiments. We’ve also asked students to join the fun by taking part in activities they can try along the way. For example, in [Chapter 6](#), they try out a quick sensory adaptation activity. In [Chapter 12](#), they try matching expressions to faces and test the

- effects of different facial expressions on themselves.
- **Critical examinations of pop psychology** spark interest and provide lessons in thinking critically about everyday topics. For example, [Chapter 6](#) scrutinizes ESP, and [Chapter 8](#) explores the controversy over the alleged repression of painful memories.

FIGURE 6 Sample “Thinking Critically About” infographic from [Chapter 12](#)

See [TABLE 5](#) for a complete list of this text’s coverage of critical thinking topics.

TABLE 5

Critical Thinking and Scientific Inquiry

Critical thinking coverage and in-depth stories of psychology’s process of scientific inquiry can be found on the following pages:		
<i>Thinking Critically About . . .</i>		
<i>infographics:</i>		
The Scientific Attitude, p. 4	Can hypnosis be therapeutic?	Why we dream, pp. 108–110
Correlation and Causation, p. 33	Alleviate pain?, pp. 250–251	Twin and adoption studies, pp. 129–133
Using More Than 10	Is there extrasensory perception?, pp. 257–259	How a child’s mind develops, pp. 174–180

Percent of Our Brain, p. 79	Do other species have language?, pp. 352–353	How do we see in color?, pp. 228–230
Tolerance and Addiction, p. 113	Do violent video games teach social scripts for violence?, pp. 508–509	Parallel processing, pp. 231–232
Gender Bias in the Workplace, p. 154	How valid is the Rorschach test?, p. 534	Is hypnosis an extension of normal consciousness or an altered state?, pp. 250–251
Parenting Styles, p. 190	Is Freud credible?, pp. 535–536	How are memories constructed?, pp. 300–305
Subliminal Sensation and Subliminal Persuasion, p. 217	Is repression a myth?, p. 536	How do we store memories in our brains?, pp. 306–311
The Effects of Viewing Media Violence, p. 293	Is psychotherapy effective?, pp. 625–628	Do other species exhibit language?, pp. 352–353
Can Memories of Childhood Sexual Abuse Be Repressed and Then Recovered?, p. 325	Evaluating alternative therapies, pp. 629–630	Aging and intelligence, pp. 373–374
The Fear Factor, p. 335	Thinking Critically With Psychological Science:	Why do we feel hunger?, pp. 396–398
Cross-Sectional and Longitudinal Studies, p. 372	“Critical thinking” introduced as a key term, p. 3	What determines sexual orientation?, pp.
The Challenges of Obesity and Weight Control, p. 401	The limits of common	
Lie Detection, p. 432

Our “How Would You Know?” Research Activities Teach Scientific Literacy Skills

We [DM and ND] created these online activities to engage students in the scientific process, showing them how psychological research begins with a question, and how key decision points can alter the meaning and value of a psychological study. In a fun, interactive environment, students learn about important aspects of research design and interpretation, and develop scientific literacy and critical thinking skills in the process. I [ND] have enjoyed taking the lead on this project and sharing my research experience and enthusiasm with students. Topics include: “How Would You Know If a Cup of Coffee Can Warm Up Relationships?,” “How Would You Know If People Can Learn to Reduce Anxiety?,” and “How Would You Know If Schizophrenia Is Inherited?”

7 “Coverage of gender, gender-identity, and cultural diversity is

very important for my course.”

Throughout this text and its resources, students will see evidence of our human kinship. Yet they will also ([TABLE 6](#) and [TABLE 7](#)) better understand the dimensions of our diversity—our *individual* diversity, our *gender* and *gender identity* diversity, and our *cultural* and *ethnic* diversity. [Table 6](#) lists the coverage of gender and gender identity. [Table 7](#) provides the integrated coverage of cultural and ethnic diversity. Significant coverage is presented within the narrative. In addition, an abundance of photos and examples throughout the text and its resources showcases the diversity of individuals within North America and across the globe.

TABLE 6

The Psychology of Gender, Gender Identity, and Sexuality

Coverage of the psychology of gender, gender identity, and sexuality can be found on the following pages:		
Absolute thresholds, pp. 215–216	Gender:	Prejudice, p. 500
ADHD, p. 567	and child raising, pp. 160–161	Psychological disorders, rate of, pp. 570–57
Adulthood: physical changes, p. 202	definition, p. 152	PTSD: development c pp. 576, 578–5
Aggression, pp. 153, 504–506	development, pp. 152–156	Rape, pp. 407, 503–504
father absence, p. 507	identity, 160–161	Religiosity and lif expectancy, pp. 473–474
pornography, p. 508	prejudice, p. 500	REM sleep, arou in, p. 98
rape, p. 508	“missing women,” p. 500	Romantic love, p. 515–517
Alcohol:	roles, pp. 159–160	
and addiction, p. 114	similarities/differences, pp. 152–156	
and sexual aggression, pp.	Gendered brain, pp. 407, 412	

114–115	Generalized anxiety disorder, p. 573	Rumination, p. 51
use, pp. 114–115	Generic pronoun “he,” p. 355	Savant syndrome, p. 361
Altruism, p. 519	Grief, pp. 211–212	Schizophrenia, p. 594
Androgyny, p. 160	Group polarization, p. 494	Self-injury, p. 590
Antisocial personality disorder, p. 602	Happiness, pp. 448–449	Sense of smell, p. 253
Attraction, pp. 511–515	Hearing loss, pp. 244, 350	Sex: definition, p. 152
Attractiveness, pp. 511–514	Hormones and:	Sex reassignment, pp. 158–159, 161, 382
Autism spectrum disorder, pp. 181–182	aggression, pp. 505–506	Sexual abuse, pp. 158, 187, 325
Behavior, pp. 435–436	sexual behavior, pp. 403–404	Sexual attraction, pp. 141–142, 409–410, 513–514
Biological predispositions in color perceptions, p. 229	sexual development, pp. 157–159, 192–193	Sexual dysfunctions, p. 405
Biological sex, pp. 156–159	testosterone-replacement therapy, p. 403	Sexual fantasies, p. 407
Bipolar disorder, pp. 583–584	Intelligence, p. 382	Sexual orientation, pp. 409–415

8 “We need to keep costs down for students, and use a book that has manageable length.”

Students deserve the highest quality educational resources at an affordable cost. Macmillan Learning has made a big effort to reduce production costs for our texts, which has allowed them to significantly reduce costs to students—especially for loose-leaf and digital options. See

[MacmillanLearning.com/Catalog/page/affordable-solutions](https://www.macmillanlearning.com/Catalog/page/affordable-solutions).

It helps that we’ve reduced length somewhat in this twelfth edition—in part due to a more efficient design. This edition is about 50 pages shorter, so it is also more manageable for those who cover all the topics in one term. In my [ND’s] recent course, ***I only required the LaunchPad key—giving students access to the e-book and online resources***. Students had the option of also purchasing a loose-leaf version of the text. The result? In addition to loving the text and online resources, ***9 in 10 students felt that the price was fair***.

You may be interested in customizing print or digital resources as a way to save costs for your students, to provide materials for your course that match your syllabus more closely, or to add your own or other Macmillan resources to your resource package. We were pleased to learn that our custom options are now available for even the smallest of courses via a new “Worth Select” program, which is part of Macmillan’s broad Curriculum Solutions program.

9 “I have a lot of nursing and pre-med students. I need a book that maps well onto the new MCAT’s psychology section.”

Since 2015, the Medical College Admission Test (MCAT) has devoted 25 percent of its questions to the “Psychological, Social, and Biological Foundations of Behavior,” with most of those questions coming from the psychological science taught in introductory psychology courses. From 1977 to 2014, the MCAT focused on biology, chemistry, and physics. Hereafter, reported the *Preview Guide for MCAT 2015*, the exam will also recognize “the importance of socio-cultural and behavioral determinants of health and health outcomes.” The exam’s new psychology section beautifully matches this text’s topics. For example, see [TABLE 8](#), which outlines the precise correlation between this text’s coverage of Emotion and Stress, and the corresponding portion of the MCAT exam. In addition, our Test Bank questions are keyed to MCAT topics. To improve their MCAT preparation, I [ND] regularly teach premedical students an intensive course covering the topics that appear in this text. For a complete pairing of the new MCAT psychology topics with this book’s contents, see MacmillanLearning.com.

TABLE 8

Sample MCAT Correlation With *Psychology*, Twelfth Edition

MCAT 2015	<i>Psychology</i> , Twelfth Edition Correlations	Page Number
Content Category 6C: Responding to the world		
Emotion	Emotion: Introduction to Emotion, Expressing	425–450

	Emotion, Experiencing Emotion	
Three components of emotion (i.e., cognitive, physiological, behavioral)	Emotion: Arousal, Behavior, and Cognition	426–430
Universal emotions (e.g., fear, anger, happiness, surprise, joy, disgust, and sadness)	Culture and Emotional Expression—including the universal emotions	436–438
	Experiencing Emotion—including the basic emotions	440–450
Adaptive role of emotion	Emotion as the body's adaptive response	454–456
	Emotions and the Autonomic Nervous System	431
Theories of emotion		
<i>James-Lange theory</i>	<i>James-Lange Theory: Arousal Comes Before Emotion</i>	427
<i>Cannon-Bard theory</i>	<i>Cannon-Bard Theory: Arousal and Emotion Occur Simultaneously</i>	427
<i>Schachter-Singer theory</i>	<i>Schachter and Singer Two-Factor Theory: Arousal + Label = Emotion</i>	428

The role of biological processes in perceiving emotion	Emotions and the Autonomic Nervous System	<u>431</u>
<i>Brain regions involved in the generation and experience of emotions</i>	Emotions and the Autonomic Nervous System	<u>431</u>
	The Physiology of Emotions—including the brain's pathways for emotions	<u>431–433</u>
<i>The role of the limbic system in emotion</i>	<i>Emotions and the Autonomic Nervous System</i>	<u>431–433</u>
	<i>The Physiology of Emotions</i>	<u>431</u>
<i>Emotion and the autonomic nervous system</i>	Emotions and the Autonomic Nervous System	<u>431</u>
<i>Physiological markers of emotion (signatures of emotion)</i>	The Physiology of Emotions	<u>431–433</u>
Stress	Stress and Illness	<u>450–462</u>
The nature of stress	Stress: Some Basic Concepts	<u>451–455</u>
<i>Appraisal</i>	<i>Stress appraisal</i>	<u>451</u>
<i>Different types of stressors (i.e., cataclysmic events, personal)</i>	<i>Stressors—Things That Push Our Buttons</i>	<u>451–454</u>

<i>Effects of stress on psychological functions</i>	<i>The Stress Response System</i>	<u>454–455</u>
Stress outcomes/response to stressors	The Stress Response System	<u>454–455</u>
<i>Physiological</i>	The Stress Response System	<u>454–455</u>
	Stress and Vulnerability to Disease	<u>456–462</u>
<i>Emotional</i>	<i>Stress and Heart Disease—Type A/B, anger management</i>	<u>459–461</u>
	Coping With Stress	<u>463–469</u>

Managing stress (e.g., exercise, relaxation techniques, spirituality)	Reducing Stress— aerobic exercise, relaxation/meditation, faith communities	<u>469–476</u>

10 “I am eager to use more digital resources but uncertain how to proceed, and in need of assistance

in this process.”

With up to 350 students in my [ND's] classes, I, too, worried about switching to Launch-Pad a couple of years ago. I spent a bit of extra time the first semester learning about all of the available resources. But it was worth it. LaunchPad has saved me time and allowed me to do things that I thought were impossible with so many students. For example, I now offer a first-day-of-class, gradable assignment in LaunchPad to get students immediately engaged. I also use frequent quizzes throughout the course, which helps my students and me to track their learning progress. LaunchPad has helped make my course a success. *Assigning* materials shows that I value these resources, and I've been delighted to see a significant improvement in student retention rates since I started using LaunchPad.

The best way to get started is to visit LaunchPadWorks.com. Then, contact your local Macmillan Learning representative and ask for an appointment with one of our Learning Solutions Specialists.

In Appreciation

“Nothing we ever do, however virtuous, can be accomplished alone.”

~ Reinhold Niebuhr, 1952

Our authoring is a collective enterprise. Aided by input from thousands of instructors and students over the years, this has become a better, more effective, more accurate book than two authors alone (these authors at least) could write. Our indebtedness continues to the innumerable researchers who have been so willing to share their time and talent to help us accurately report their research, and to the hundreds of instructors who have taken the time to offer feedback. We empathize with the long-time *Atlantic* writer, James Fallows’ observation that “In this business you spend most of your time talking with people who *know more* about a given subject than you do. That is in hopes of eventually being able to explain it to people who know less.”

Our gratitude extends to the colleagues who contributed criticism, corrections, and creative ideas related to the content and effectiveness of this new edition and its resources. For their expertise and encouragement, and the gift of their time to the teaching of psychology, we thank the reviewers and consultants listed here.

At Worth Publishers a host of people played key roles in creating this twelfth edition.

Executive Program Manager Carlise Stembridge has been a valued team leader, thanks to her dedication, creativity, and sensitivity. Carlise oversees, encourages, and guides our author-editor team, and she serves as an important liaison with our colleagues in the field.

Noel Hohnstine and Laura Burden expertly coordinated creation of the media resources. Betty Probert efficiently edited and produced the Test Bank

questions (working with Chrysalis Wright, University of Central Florida), Instructor's Resources, and Lecture Guides and, in the process, helped fine-tune the whole book. Katie Pachnos provided terrific support in commissioning and organizing the multitude of reviews, coordinating our development and production schedules, and providing editorial guidance. Lee McKevitt did a splendid job of laying out each page. Robin Fadool and Lisa Passmore worked together to locate the myriad photos, and Michael McCarty coordinated the permissions process for our Instructor's Resources. Art Manager Matt McAdams managed the updating of our art program, and worked with artist Evelyn Pence to create the wonderful new Thinking Critically About infographics.

Content Project Manager Won McIntosh and Senior Workflow Supervisor Susan Wein masterfully kept the book to its tight schedule, and Senior Design Manager Vicki Tomaselli skillfully directed creation of the beautiful new design.

Christine Brune, chief editor for the last three decades, is a wonder worker. She offers just the right mix of encouragement, gentle admonition, attention to detail, and passion for excellence. An author could not ask for more. Development editors Nancy Fleming, Trish Morgan, and Danielle Slevens amazed us with their meticulous focus, impressive knowledge, and helpful editing—and with kindred spirits to our own. And Deborah Heimann did an excellent job with the copyediting. After their several thousand hours of world-class skill invested in guiding and shaping this book, we fully appreciate Helen Keller's surmise that "Alone we can do so little. Together we can do so much."

To achieve our goal of supporting the teaching of psychology, these resources not only must be authored, reviewed, edited, and produced, but also made available to teachers of psychology. For their exceptional success in doing that, our author team is grateful to Macmillan Learning's professional sales and marketing team. We are especially grateful to Executive Marketing Manager Kate Nurre, Senior Marketing Manager Lindsay Johnson, and Learning Solutions Specialists Nicki Trombley and Robyn Burnett for tirelessly working to inform our teaching colleagues of our efforts to assist their teaching, and for the joy of working with them.

At Hope College, the supporting team members for this edition included Kathryn Brownson, who researched countless bits of information and edited

and proofed hundreds of pages. Kathryn is a knowledgeable and sensitive adviser on many matters, and Sara Neevel is our high-tech manuscript developer, par excellence. At the University of Kentucky, Lorie Hailey has showcased a variety of indispensable qualities, including a sharp eye and a strong work ethic.

Again, I [DM] gratefully acknowledge the editing assistance and mentoring of my writing coach, poet Jack Ridl, whose influence resides in the voice you will be hearing in the pages that follow. He, more than anyone, cultivated my delight in dancing with the language, and taught me to approach writing as a craft that shades into art. Likewise, I [ND] am grateful to my intellectual hero and mentor, Roy Baumeister, who taught me how to hone my writing and embrace the writing life. I'm also indebted to John Tierney, who has offered unending support and served as a role model of how to communicate to a general audience.

And we have enjoyed our ongoing work with each other! It has been a joy for me [DM] to welcome Nathan into this project. Nathan's fresh insights and contributions are enriching this book as we work together on each chapter—every day, every month, every year. With support from our wonderful editors, this is a team project. In addition to our work together on the textbook, Nathan and I contribute to the monthly “Teaching Current Directions in Psychological Science” column in the *APS Observer* (tinyurl.com/MyersDeWall). I [DM] also blog at TalkPsych.com, where I share exciting new findings, everyday applications, and observations on all things psychology.

Finally, our gratitude extends to the many students and instructors who have written to offer suggestions, or just an encouraging word. It is for them,

and those about to begin their study of psychology, that we have done our best to introduce the field we love.

* * *

The day this book went to press was the day we started gathering information and ideas for the next edition. Your input will influence how this book continues to evolve. So, please, do share your thoughts.

Set Specific, Realistic Daily Goals

Don't Forget About Rewards!

Do You Need to Revise Your New Schedule?

Are You Doing Well in Some Courses But Not in Others?

Have You Received a Poor Grade on a Test?

Are You Trying to Study Regularly for the First Time and Feeling Overwhelmed?

We all face challenges in our schedules. This might be your first time living outside of your parents' home, leaving you unsure how to juggle your school and social commitments. Some of you may be taking night classes, others squeezing in an online course between jobs or after putting children to bed at night. Some of you may be veterans using military benefits to jump-start a new life. Whatever your situation, the transition from your previous life situation to this one presents some challenges.

How can you balance all of your life's demands and be successful? Time management. Manage the time you have so that you can find the time you need.

In this section, I will outline a simple, four-step process for improving the way you make use of your time.

- . Keep a time-use diary to understand how you are using your time. You may be surprised at how much time you're wasting.
- . Design a new schedule for using your time more effectively.
- . Make the most of your study time so that your new schedule will work for you.
- . If necessary, refine your new schedule, based on what you've learned.

How Are You Using Your Time Now?

Although everyone gets 24 hours in the day and seven days in the week, we fill those hours and days with different obligations and interests. If you are like most people, you probably use your time wisely in some ways, and not so wisely in others. Answering the questions in [TABLE 1](#) can help you find trouble spots—and hopefully more time for the things that matter most to you.

TABLE 1
Study Habits Survey

--

Answer the following questions, writing Yes or No for each line.

1. Do you usually set up a schedule to budget your time for studying, work, recreation, and other activities? _____
2. Do you often put off studying until time pressures force you to cram? _____
3. Do other students seem to study less than you do, but get better grades? _____
4. Do you usually spend hours at a time studying one subject, rather than dividing that time among several subjects? _____
5. Do you often have trouble remembering what you have just read in a textbook? _____
6. Before reading a chapter in a textbook, do you skim through it and read the section headings? _____
7. Do you try to predict test questions from your class notes and reading? _____
8. Do you usually try to summarize in your own words what you have just finished reading? _____
9. Do you find it difficult to concentrate for very long when you study? _____
10. Do you often feel that you studied the wrong material for a test? _____

Thousands of students have participated in similar surveys. Students who are fully realizing their academic potential usually respond as follows: (1) yes, (2) no, (3) no, (4) no, (5) no, (6) yes, (7) yes, (8) yes, (9) no, (10) no. Do your responses fit that pattern? If not, you could benefit from improving your time management and study habits.

The next thing you need to know is how you *actually* spend your time. To find out, record your activities in a *time-use diary* for one week. Be realistic. Take notes on how much time you spend attending class, studying, working, commuting, meeting personal and family needs, preparing and eating meals, socializing (don't forget texting, social networking, and gaming), exercising, and anything else that occupies your time, including life's small practical tasks, which can take up plenty of your time 24/7. As you record your

activities, take notes on how you are feeling at various times of the day. When does your energy slump, and when do you feel most energetic?

Design a Better Schedule

Take a good look at your time-use diary. Where do you think you may be wasting time? Do you spend a lot of time commuting, for example? If so, could you use that time more productively? If you take public transportation, commuting is a great time to read and test yourself for review. You can access the e-book anywhere, anytime!

Did you remember to include time for meals, personal care, work schedules, family commitments, and other fixed activities?

How much time do you sleep? In the battle to meet all of life's daily commitments and interests, we tend to treat sleep as optional. Do your best to manage your life so that you can get enough sleep to feel rested. It's hard to achieve your goals if you don't have the energy to complete them. You will feel better and be healthier, and you will also do better academically and in relationships with your family and friends. (You will read more about this in [Chapter 3](#).)

Are you dedicating enough time for focused study? Take a last look at your notes to see if any other patterns pop out. Now it's time to create a new and more efficient schedule.

Plan the Term

Before you draw up your new schedule, think ahead. If your course is not already online—complete with a schedule of assignments, activities, quizzes, and exams for the term—use your phone’s calendar feature, or buy a portable calendar. Enter the dates of all exams and assignments. Also be sure to track your own long-range personal plans, including work and family commitments. Keep your personal calendar up-to-date, refer to it often, and change it as needed. Through this process, you will develop a regular schedule that will help you achieve success.

Plan Your Week

To pass those exams, meet those deadlines, and keep up with your life outside of class, you will need to convert your long-term goals into a daily schedule. Be realistic—you will be living with this routine for the entire school term. Here are some more things to add to your personal calendar.

- . Enter your class times, work hours, and any other fixed obligations. Be thorough. Allow plenty of time for such things as commuting, meals, and laundry.
- . Set up a study schedule for each course. Remember what you learned about yourself in the study habits survey ([Table 1](#)) and your time-use diary.
- . After you have budgeted time for studying, fill in slots for other obligations, exercise, fun, and relaxation.

More Tips for Effective Scheduling

There are a few other things you will want to keep in mind when you set up your schedule.

Spaced study is more effective than massed study. If you need 3 hours to study one subject, for example, it’s best to divide that into shorter periods spaced over several days.

Alternate subjects, but avoid interference. Alternating the subjects you study in any given session will keep you fresh and will, surprisingly, increase your ability to remember what you’re learning in each different

area. Studying similar topics back-to-back, however, such as two different foreign languages, could lead to interference in your learning. (You will hear more about this in [Chapter 8](#).)

Determine the amount of study time you need to do well in each course. The time you need depends on the difficulty of your courses and the effectiveness of your study methods. Ideally, you would spend at least 1 to 2 hours studying for each hour spent in class. Increase your study time slowly by setting weekly goals that will gradually bring you up to the desired level.

Create a schedule that makes sense. Tailor your schedule to meet the demands of each course. For the course that emphasizes lecture notes, plan a daily review of your notes soon after each class. If you are evaluated for class participation (for example, in a language course), allow time for a review just before the class meets. Schedule study time for your most difficult (or least motivating) courses during hours when you are the most alert and distractions are fewest.

Schedule open study time. Life can be unpredictable. Emergencies and new obligations can throw off your schedule. Or you may simply need some extra time for a project or for review in one of your courses. Try to allow for some flexibility in your schedule each week.

The Importance of Playing Offense

We can't control everything. Car troubles, family problems, and work challenges happen. Sometimes it seems as if we have to play "defense" against the demands and problems that can pile up, leaving us stressed out and unable to achieve our goals. There is a solution: Play "offense" against your environment. Set out with a plan for each day, rather than just letting the day happen to you. You will then have a lot more control over how you spend your time. Establishing routines and making decisions in advance actually conserves energy, as it spares us from some of our daily decision making. If we know we are going to study two hours in the morning before class, we won't waste time and energy weighing the pros and the cons of that choice over breakfast each day.

When you kept your time-use diary, I recommended that you track the times you feel most energetic. Keep that in mind as you plan your days. Try to match your high-energy times with your most challenging school work and projects. And don't forget to replenish your energy along the way with meals, rest, and social time.

Following these guidelines will help you find a schedule that works for you!

Make Every Minute of Your Study Time Count

How do you study from a textbook? We've learned a lot about effective study techniques from cognitive psychologists. To get the most out of your text, avoid simply reading and rereading in a passive manner. That method may cause you to remember the wrong things—the catchy stories but not the main points that show up later in test questions. And it's clearer than ever that taking effective class notes is essential. Here are some tips that will help you get the most from your text resources and your class.

Use SQ3R to Help You Master This Text

David Myers and Nathan DeWall organized this text by using a system called SQ3R (Survey, Question, Read, Retrieve, Review). Using SQ3R can help you to understand what you read, and to retain that information longer.

Applying SQ3R may feel at first as though it's taking more time and effort to “read” a chapter, but with practice, these steps will become automatic.

Survey

Before you read a chapter, survey its key parts. Scan the chapter outline. Note that main sections have numbered Learning Objective Questions to help you focus. Pay attention to headings, which indicate important subtopics, and to words set in bold type.

Surveying gives you the big picture of a chapter's content and organization. Understanding the chapter's logical sections will help you break your work into manageable pieces in your study sessions.

Question

To show you care about your education, continually ask questions. Doing so signals that you're engaged, curious, and motivated to work hard.

Questioning starts while you're reading. As you survey, don't limit yourself to the numbered Learning Objective Questions that appear throughout the chapter. Jotting down additional questions of your own will cause you to look at the material in a new way. (You might, for example, scan this section's headings and ask "What does 'SQ3R' mean?") Information becomes easier to remember when you make it personally meaningful. Trying to answer your questions while reading will keep you in an active learning mode.

Read

As you read, keep your questions in mind and actively search for the answers. If you come to material that seems to answer an important question that you haven't jotted down, stop and write down that new question.

Be sure to read everything. Don't skip photo or art captions, graphs, tables, or quotes. An idea that seems vague when you read about it may become clear when you see it in a graph or table. Keep in mind that instructors sometimes base their test questions on figures and tables. And take advantage of the "Thinking Critically About" infographic features that will help you learn about key concepts.

Retrieve

When you have found the answer to one of your questions, look away and mentally recite the question and its answer. Then write the answer next to the question in your own words. Trying to explain something in your own words will help you figure out where there are gaps in your understanding. These kinds of opportunities to practice *retrieving* develop the skills you will need when you are taking exams. If you study without ever putting your book and notes aside, you may develop false confidence about what you know. With the material available, you may be able to recognize the correct answer to your questions. But will you be able to recall it later, when you take an exam without having your mental props in sight?

Test your understanding as often as you can. Testing yourself is part of successful learning, because the act of testing forces your brain to work at remembering, thus establishing the memory more permanently (so you can find it later for the exam!). Use the self-testing opportunities throughout each chapter, including the periodic Retrieval Practice items. Also take advantage of the self-testing that is available in the online resources (LaunchPadWorks.com).

Review

After working your way through the chapter, read over your questions and your written answers. Take an extra few minutes to create a brief written summary covering all of your questions and answers. At the end of each main

section, you should take advantage of three important opportunities for self-testing and review—a list of that section’s Learning Objective Questions for you to try answering before checking [Appendix C](#) (Complete Chapter Reviews), a list of that section’s key terms for you to try to define before checking the referenced page, and a set of Mastering the Material test questions that cover all of that section’s key concepts (with answers in [Appendix D](#)).

Take Useful Class Notes

Good notes will boost your understanding and retention. Are yours thorough? Do they form a sensible outline of what you learned in each class? If not, you may need to make some changes.

Keep Each Course’s Notes Separate and Organized

Keeping all your notes for a course in one location will allow you to easily find answers to questions. Three options are (1) separate notebooks for each course, (2) clearly marked sections in a shared ring binder, or (3) carefully organized folders if you opt to take notes electronically. For the print options, removable pages will allow you to add new information and weed out past mistakes. Choosing notebook pages with lots of space, or using mark-up options in electronic files, will allow you to add comments when you review and revise your notes after class.

Use an Outline Format

Use roman numerals for major points, letters for supporting arguments, and so on. (See [FIGURE 1](#) for a sample.) Creating an outline from what you’ve learned in class will help you to put the information in context and to see the key takeaway points.

			When is my daily peak in circadian arousal? Study hardest subject then!
○	Sleep (Chapter 3)		
	I. Biological Rhythms		
	A. Circadian Rhythm (circa-about; dlem-day)—24-hour cycle.		
	1. Ups and downs throughout day/night.		
	Dip in afternoon (siesta time).		
	2. Melatonin—hormone that makes us sleepy. Produced by pineal gland in brain. Bright light shuts down production of melatonin.		
	(Dim the lights at night to get sleepy.)		
	B. FOUR Sleep Stages, cycle through every 90 minutes all night! Aserinsky discovered—his son—REM sleep (dreams, rapid eye movement, muscles paralyzed but brain super active). EEG measurements showed sleep stages.		
○	1. NREM-1 (non-Rapid Eye Movement sleep; brief, images like hallucinations; hypnagogic jerks)		
	2. NREM-2 (harder to waken, sleep spindles)		
	3. NREM-3 (DEEP sleep—hard to wake up! Long slow waves on EEG; bedwetting, night terrors, sleepwalking occurs here; asleep but not dead—can still hear, smell, etc. Will wake up for baby.)		
	4. REM Sleep (Dreams...)		

FIGURE 1 Sample class notes in outline form

Here is a sample from a student's notes taken in outline form from a class that was focused on sleep.

Clean Up Your Notes After Class

Try to reorganize your notes soon after class. Expand or clarify your comments and clean up any unclear phrases while the material is fresh in your mind. Write important questions in the margin, or by using an electronic markup feature, next to notes that answer them. (For example: “What are the sleep stages?”) This will help you when you review your notes before a test.

Create a Study Space That Helps You Learn

It's easier to study effectively if your work area is well designed.

Organize Your Space

Work at a desk or table, not on your bed or a comfy chair that will tempt you to nap.

Minimize Distractions

Turn the TV off, turn off your phone and its notifications, and close distracting windows on your computer. If you must listen to music to mask outside noise, play soft instrumentals, not vocal selections that will draw your mind to the lyrics.

Ask Others to Honor Your Quiet Time

Tell roommates, family, and friends about your new schedule. Try to find a study place where you are least likely to be disturbed. Quiet places do exist. Sometimes you just need to do a little detective work to find them.

Set Specific, Realistic Daily Goals

The simple note “7–8 P.M.: Study Psychology” is too broad to be useful. Instead, break your studying into manageable tasks. For example, you will want to subdivide large reading assignments. If you aren’t used to studying for long periods, start with relatively short periods of concentrated study, with breaks in between. In this text, for example, you might decide to read one major section before each break. Limit your breaks to 5 or 10 minutes to stretch or move around a bit.

Your attention span is a good indicator of whether you are pacing yourself successfully. At this early stage, it’s important to remember that you’re in training. If your attention begins to wander, get up immediately and take a short break. It is better to study effectively for 15 minutes and then take a break than to fritter away 45 minutes out of your study hour. As your endurance develops, you can increase the length of study periods.

Don’t Forget About Rewards!

If you have trouble studying regularly, giving yourself a reward may help.

What kind of reward works best? That depends on what you enjoy. You might start by making a list of 5 or 10 things that put a smile on your face. Spending time with a loved one, taking a walk or going for a bike ride, relaxing with a magazine or novel, or watching a favorite show can provide immediate rewards for achieving short-term study goals.

To motivate yourself when you're having trouble sticking to your schedule, allow yourself an immediate reward for completing a specific task. If running makes you smile, change your shoes, grab a friend, and head out the door! You deserve a reward for a job well done.

Do You Need to Revise Your New Schedule?

What if you've lived with your schedule for a few weeks, but you aren't making progress toward your academic and personal goals? What if your studying hasn't paid off in better grades? Don't despair and abandon your program, but do take a little time to figure out what's gone wrong.

Are You Doing Well in Some Courses But Not in Others?

Perhaps you need to shift your priorities a bit. You may need to allow more study time for chemistry, for example, and less time for some other course.

Have You Received a Poor Grade on a Test?

Did your grade fail to reflect the effort you spent preparing for the test? This can happen to even the hardest-working student, often on a first test with a new instructor. This common experience can be upsetting. "What do I have to do to get an A?" "The test was unfair!" "I studied the wrong material!"

Try to figure out what went wrong. Analyze the questions you missed, dividing them into two categories: class-based questions and text resource-based questions. How many questions did you miss in each category? If you find far more errors in one category than in the other, you'll have some clues

to help you revise your schedule. Depending on the pattern you've found, you can add extra study time to the review of class notes, or to studying the text resources.

Are You Trying to Study Regularly for the First Time and Feeling Overwhelmed?

Perhaps you've set your initial goals too high. Remember, the point of time management is to identify a regular schedule that will help you achieve success. Like any skill, time management takes practice. Accept your limitations and revise your schedule to work slowly up to where you know you need to be—perhaps adding 15 minutes of study time per day.

* * *

I hope that these suggestions help make you more successful academically, and that they enhance the quality of your life in general. Having the necessary skills makes any job a lot easier and more pleasant. Let me repeat my warning not to attempt to make too drastic a change in your lifestyle immediately. Good habits require time and self-discipline to develop. Once established, they can last a lifetime.

REVIEW Student Preface: Time Management—How to Be a Great Student and Still Have a Life

How Are You Using Your Time Now?

- Identify your areas of weakness.
- Keep a time-use diary.
- Record the time you actually spend on activities.
- Record your energy levels to find your most productive times.

Design a Better Schedule

- Decide on your goals for the term and for each week.

- Enter class times, work times, social times (for family and friends), and time needed for other obligations and for practical activities.
- Tailor study times to avoid interference and to meet each course's needs.
- Play offense with your schedule, so that you take control and use your energy efficiently.

Make Every Minute of Your Study Time Count

- Use the SQ3R system (survey, question, read, retrieve, review) to master material covered in your text.
- Take careful notes (in outline form) that will help you recall and rehearse what you learned in class.
- Try to eliminate distractions to your study time, and ask friends and family to help you focus on your work.
- Set specific, realistic daily goals to help you focus on each day's tasks.
- When you achieve your daily goals, reward yourself with something that you value.

Do You Need to Revise Your New Schedule?

- Allocate extra study time for courses that are more difficult, and a little less time for courses that are easy for you.
 - Analyze your test results to help determine a more effective balance in how you spend your study time.
 - Make sure your schedule is not too ambitious. Gradually establish a schedule that will be effective for the long term.
-

PROLOGUE

The Story of Psychology

PeopleImages/Getty Images

What Is Psychology?

Psychology Is a Science

THINKING CRITICALLY ABOUT: The Scientific Attitude

Critical Thinking

Psychological Science Is Born

Psychological Science Develops

Contemporary Psychology

Use Psychology to Become a Stronger Person—and a Better Student

Harvard astronomer Owen Gingerich has described the human brain as “by far the most complex physical object known to us in the entire cosmos” (2006, p. 29). On the scale of outer space, we are less than a single grain of

sand on all the oceans' beaches, and our lifetime is but a relative nanosecond. Yet there is nothing more awe inspiring than our own inner space. Our consciousness—our mind somehow arising from matter—remains a profound mystery. Our thinking, emotions, and actions (and their interplay with others' thinking, emotions, and actions) fascinate us. Outer space staggers us with its enormity. But inner space enthralls us. Enter psychological science.

From news and popular media portrayals, you might think that psychologists analyze personality, offer counseling, dispense child-raising advice, examine crime scenes, and testify in court. Do they? Yes, and much more. Consider some of psychology's questions that you may wonder about:

- Have you ever found yourself reacting to something as one of your biological parents would—perhaps in a way you vowed you *never* would—and then wondered how much of your personality you inherited? *To what extent do genes predispose our individual differences in personality? How do home and community environments shape us?*
- Have you ever worried about how to act among people of a different culture, race, gender identity, or sexual orientation? *In what ways are we alike as members of the human family? How do we differ?*
- Have you ever awakened from a nightmare and wondered why you had such a crazy dream? *Why do we dream?*
- Have you ever played peekaboo with a 6-month-old and wondered why the baby finds your disappearing/reappearing act so delightful? *What do babies actually perceive and think?*
- Have you ever wondered what fosters school and work success? *Does inborn intelligence explain why some people get richer, think more creatively, or relate more sensitively? Or does gritty effort, and a belief that we can grow smarter, matter more?*
- Have you ever become depressed or anxious and wondered whether you'll ever feel "normal"? *What triggers our bad moods—and our good ones? What's the line between a normal mood swing and a psychological disorder?*

Psychology is a science that seeks to answer such questions about us all—how and why we think, feel, and act as we do.

What Is Psychology?

Once upon a time, on a planet in our neighborhood of the universe, there came to be people. Soon thereafter, these creatures became intensely interested in themselves and in one another: “Who are we? What produces our thoughts? Our feelings? Our actions? And how are we to understand and manage those around us?”

Psychology Is a Science

LOQ **LEARNING OBJECTIVE QUESTION** **P-1** How is psychology a science, and why is it the “rat is always right”?

To assist your active learning of psychology, numbered Learning Objectives, framed as questions, appear at the beginning of major sections. You can test your understanding by trying to answer the question before, and then again after, you read the section.

Throughout the text, important concepts are **boldfaced**. As you study, you can find these terms with their definitions in a nearby margin and in the Glossary at the end of the book. (In the e-book, definitions are always a click away.)

Underlying all science is, first, a passion to explore and understand without misleading or being misled. Some questions (*Is there life after death?*) are beyond science. Answering them in any way requires a leap of faith. With many other ideas (*Can some people demonstrate ESP?*), the proof is in the pudding. Let the facts speak for themselves.

Magician James Randi has used this [empirical approach](#) when testing those claiming to see glowing auras around people’s bodies:

Randi: Do you see an aura around my head?

Aura seer: Yes, indeed.

Randi: Can you still see the aura if I put this magazine in front of my face?

Aura seer: Of course.

Randi: Then if I were to step behind a wall barely taller than I am, you could determine my location from the aura visible above my head, right?

empirical approach an evidence-based method that draws on observation and experimentation.

Randi once told me (DM) that no aura seer had agreed to take this simple test.

No matter how sensible-seeming or how wild an idea, the smart thinker asks: *Does it work?* When put to the test, can its predictions be confirmed? Subjected to such scrutiny, crazy-sounding ideas sometimes find support. During the 1700s, scientists scoffed at the notion that meteorites had extraterrestrial origins. When two Yale scientists challenged the conventional opinion, Thomas Jefferson reportedly jeered, “Gentlemen, I would rather believe that those two Yankee professors would lie than to believe that stones fell from Heaven.” Sometimes scientific inquiry turns jeers into cheers.

More often, science becomes society’s garbage collector, sending crazy-sounding ideas to the waste heap, atop previous claims of perpetual motion machines, miracle cancer cures, and out-of-body travels into centuries past. To sift reality from fantasy, sense from nonsense, requires a *scientific attitude*: being skeptical but not cynical, open but not gullible. When ideas compete, careful testing can reveal which ones best fit the facts. Can astrologers predict your future based on the planets’ position at your birth? Is electroconvulsive therapy (delivering an electric shock to the brain) an effective treatment for severe depression? As we will see, putting such claims to the test has led psychological scientists to answer *No* to the first question and *Yes* to the second.

Reprinted by permission of Universal Press Syndicate. © 1997 Wiley.

Putting a scientific attitude into practice requires not only curiosity and skepticism but also humility—an awareness of our own vulnerability to error and an openness to new perspectives. What matters is not my opinion or yours, but the truths revealed by our questioning and testing. If people or other animals don’t behave as our ideas predict, then so much the worse for our ideas. This humble attitude was expressed in one of psychology’s early mottos: “The rat is always right.” (See Thinking Critically About: The Scientific Attitude.)

LOQ P-2 What are the three key elements of the scientific attitude, and how do they support scientific inquiry?

Thinking Critically About: The Scientific Attitude

Three basic attitudes helped make modern science possible.

1 CURIOSITY:

Does it work?

When put to the test, can its predictions be confirmed?

Can some people read minds? •

Are stress levels related to health and well-being? •

- No one has yet been able to demonstrate extrasensory mind-reading.
- Many studies have found that higher stress relates to poorer health.

2 SKEPTICISM:

What do you mean?

How do you know?

Sifting reality from fantasy requires a healthy skepticism—an attitude that is not cynical (doubting everything), but also not gullible (believing everything).

Do our facial expressions and body postures affect how we actually feel? •

Do parental behaviors determine children's sexual orientation—or not? •

- Our facial expressions and body postures can affect how we feel.
- As you will see in Chapter 11, there is not a relationship between parental behaviors and a child's sexual orientation.

3 HUMILITY:

Researchers must be willing to be surprised and follow new ideas. People and other animals don't always behave as our ideas and beliefs would predict.

The rat is always right.

Critical Thinking

LOQ P-3 How does critical thinking feed a scientific attitude, and smarter thinking for everyday life?

The scientific attitude—curiosity + skepticism + humility—prepares us to think smarter. Smart thinking, called **critical thinking**, examines assumptions, appraises the source, discerns hidden biases, evaluates evidence, and assesses conclusions. Whether reading a research report or an online opinion, or listening to news or a talk show, critical thinkers ask questions: *How do they know that? What is this person's agenda? Is the conclusion based on anecdote, or on evidence? Does the evidence justify a cause-effect conclusion? What alternative explanations are possible?*

critical thinking thinking that does not blindly accept arguments and conclusions. Rather, it examines assumptions, appraises the source, discerns hidden biases, evaluates evidence, and assesses conclusions.

From a Twitter feed:

“The problem with quotes on the Internet is that you never know if they’re true.”

Abraham Lincoln

Critical thinkers wince when people make factual claims based on gut intuition: “I *feel like* climate change is [or isn’t] happening.” “I *feel like* self-driving cars are more [or less] dangerous.” “I *feel like* my candidate is more honest.” Such beliefs (commonly mislabeled as feelings) may or may not be true. Critical thinkers are open to the possibility that they might be wrong. Sometimes, the best evidence confirms our intuitions. Sometimes it challenges them, and beckons us to a different way of thinking.

Critical thinking, informed by science, helps clear the colored lenses of our biases. Consider: Does climate change threaten our future, and, if so, is it human-caused? In 2016, climate-action advocates interpreted record Louisiana flooding as evidence of climate change. In 2015, climate-change

skeptics perceived North American bitter winter cold as discounting global warming. Rather than having their understanding of climate change swayed by such examples of today's weather, critical thinkers say, "Show me the evidence." Over time, is the Earth actually warming? Are the polar ice caps melting? Are vegetation patterns changing? And is human activity emitting atmospheric CO₂ that would lead us to expect such changes?

"The real purpose of the scientific method is to make sure Nature hasn't misled you into thinking you know something you don't actually know."

Robert M. Pirsig, *Zen and the Art of Motorcycle Maintenance*, 1974

When contemplating such issues, critical thinkers will also consider the credibility of sources. They will look at the evidence (*Do the facts support them, or are they just makin' stuff up?*). They will recognize multiple perspectives. And they will expose themselves to news sources that challenge their preconceived ideas.

Paul Sakuma/AP Images; Photos 12/Alamy

Life after studying psychology

The study of psychology, and its critical thinking strategies, have helped prepare people for varied occupations, as illustrated by Facebook founder Mark Zuckerberg (who studied psychology and computer science while at Harvard) and Natalie Portman (who majored in psychology and co-authored a scientific article at Harvard—and on one of her summer breaks was filmed for *Star Wars: Episode I*).

Some religious people may view critical thinking and scientific inquiry, including psychology's, as a threat. Yet many of the leaders of the scientific revolution, including Copernicus and Newton, were deeply religious people acting on the idea that "in order to love and honor God, it is necessary to fully

appreciate the wonders of his handiwork” (Stark, 2003a,b).

“My deeply held belief is that if a god anything like the traditional sort exists, our curiosity and intelligence are provided by such a god. We would be unappreciative of those gifts . . . if we suppressed our passion to explore the universe and ourselves.”

Carl Sagan, *Broca's Brain*, 1979

Critical inquiry can lead us to surprising findings. Some examples from psychological science: Massive losses of brain tissue early in life may have minimal long-term effects (see [Chapter 2](#)). Within days, newborns can recognize their mother by her odor (see [Chapter 5](#)). After brain damage, a person may be able to learn new skills yet be unaware of such learning (see [Chapter 8](#)). Diverse groups—men and women, old and young, rich and middle class, those with and without disabilities—report roughly comparable levels of personal happiness (see [Chapter 12](#)).

As later chapters also illustrate, critical inquiry sometimes debunks popular presumptions. Sleepwalkers are *not* acting out their dreams (see [Chapter 3](#)). Our past experiences are *not* all recorded verbatim in our brains; with brain stimulation or hypnosis, one *cannot* simply replay and relive long-buried or repressed memories (see [Chapter 8](#)). Most people do *not* suffer from unrealistically low self-esteem, and high self-esteem is *not* all good (see [Chapter 14](#)). Opposites tend *not* to attract (see [Chapter 13](#)). In these instances and many others, what psychological scientists have learned is not what is widely believed.

Psychology's critical inquiry can also identify effective policies. To deter crime, should we invest money in lengthening prison sentences, or increase the likelihood of arrest? To help people recover from a trauma, should counselors help them relive it, or not? To increase voting, should we tell people about the low turnout problem, or emphasize that their peers are voting? What matters is not what we “feel” is true, but what *is* true. When put to critical thinking's test—and contrary to common practice—the second option in each of this paragraph's examples wins (Shafir, 2013).

Study Tip: Memory research reveals a *testing effect*: We retain

information much better if we actively retrieve it by self-testing and rehearsing. (More on this at the end of this Prologue.) To bolster your learning and memory, take advantage of the *Retrieval Practice* opportunities you'll find throughout this text—with answers for checking at the base of each page or a click away in the e-book.

RETRIEVAL PRACTICE

RP-1 Describe what's involved in critical thinking.

ANSWER: Evaluating evidence, assessing conclusions, and examining our own assumptions are essential parts of critical thinking.

Psychological Science Is Born

LOQ P-4 What were some important milestones in psychology's early development?

To be human is to be curious about ourselves and the world around us. Before 300 B.C.E., the Greek naturalist and philosopher Aristotle theorized about learning and memory, motivation and emotion, perception and personality. Today we chuckle at some of his guesses, like his suggestion that a meal makes us sleepy by causing gas and heat to collect around the source of our personality, the heart. But credit Aristotle with asking the right questions.

Roy Toft/National Geographic/Getty Images; Antonia Brune

A smile is a smile the world around

This book tells the story of psychology as a global science, one that studies and celebrates cultural and gender similarities and differences. For example, cultural norms vary in when and how often people should smile, but a naturally happy smile *means* the same thing anywhere in the world.

PSYCHOLOGY'S FIRST LABORATORY Philosophers' thinking about thinking continued until the birth of psychology as we know it. That happened on a December day in 1879, in a small, third-floor room at Germany's University of Leipzig. There, two young men were helping an austere, middle-aged professor, Wilhelm Wundt, create an experimental apparatus. Their machine measured how long it took for people to press a telegraph key after hearing a ball hit a platform (Hunt, 1993). Curiously, people responded in about one-tenth of a second when asked to press the key as soon as the sound occurred—and in about two-tenths of a second when asked to press the key as soon as they were consciously aware of perceiving the sound. (To be aware of one's awareness takes a little longer.) Wundt was seeking to measure “atoms of the mind”—the fastest and simplest mental processes. So began the first psychological laboratory, staffed by Wundt and psychology's first graduate students.

Throughout the book, information sources are cited in parentheses, with researchers' names and the date the research was published. Every citation can be found in the end-of-book References section, with complete documentation that follows American Psychological Association (APA) style.

PSYCHOLOGY'S FIRST SCHOOLS OF THOUGHT Before long, this new science of psychology became organized into different branches, or schools of thought, each promoted by pioneering thinkers. Two early schools were [structuralism](#) and [functionalism](#).

structuralism early school of thought promoted by Wundt and Titchener; used introspection to reveal the structure of the human mind.

functionalism early school of thought promoted by James and influenced by

Darwin; explored how mental and behavioral processes function—how they enable the organism to adapt, survive, and flourish.

Structuralism As physicists and chemists discerned the structure of matter, so psychologist Edward Bradford Titchener aimed to discover the mind's structure. He engaged people in self-reflective *introspection* (looking inward), training them to report elements of their experience as they looked at a rose, listened to a metronome, smelled a scent, or tasted a substance. What were their immediate sensations, their images, their feelings? And how did these relate to one another? Alas, structuralism's technique of introspection proved somewhat unreliable. It required smart, verbal people, and its results varied from person to person and experience to experience. As introspection waned, so did structuralism. Hoping to assemble the mind's structure from simple elements was rather like trying to understand a car by examining its disconnected parts.

Functionalism Philosopher-psychologist William James thought it would be more fruitful to consider the evolved functions of our thoughts and feelings. Smelling is what the nose does; thinking is what the brain does. But *why* do the nose and brain do these things? Under the influence of evolutionary theorist Charles Darwin, James assumed that thinking, like smelling, developed because it was *adaptive*—it helped our ancestors survive and reproduce. Consciousness serves a function. It enables us to consider our past, adjust to our present, and plan our future. To explore the mind's adaptive functions, James studied down-to-earth emotions, memories, willpower, habits, and moment-to-moment streams of consciousness.

James' writings moved the publisher Henry Holt to offer James a contract for a textbook on the new science of psychology. James agreed and began work in 1878, with an apology for requesting two years to finish his writing. The text proved an unexpected chore and actually took him 12 years. (Why are we not surprised?) More than a century later, people still read the resulting *Principles of Psychology* (1890) and marvel at the brilliance and elegance with which James introduced psychology to the educated public.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Wilhelm Wundt (1832–1920)

Wundt established the first psychology laboratory at the University of Leipzig, Germany.

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

Edward Bradford Titchener (1867–1927)

Titchener used introspection to search for the mind's structural elements.

PSYCHOLOGY'S FIRST WOMEN James' legacy stems from his Harvard mentoring as well as from his writing. In 1890, thirty years before American women had the right to vote, he admitted Mary Whiton Calkins into his graduate seminar—over the objections of Harvard's president (Scarborough & Furumoto, 1987). When Calkins joined, the other students (all men) dropped out. So James tutored her alone. Later, she finished all of Harvard's Ph.D. requirements, outscoring all the male students on the qualifying exams. Alas, Harvard denied her the degree she had earned, offering her instead a degree from Radcliffe College, its undergraduate “sister” school for women. Calkins resisted the unequal treatment and refused the degree. She nevertheless went on to become a distinguished memory researcher and in 1905 became the American Psychological Association's (APA's) first female president.

The honor of being the first official female psychology Ph.D. later fell to Margaret Floy Washburn, who also wrote an influential book, *The Animal Mind*, and became the second female APA president in 1921. But Washburn's gender barred doors for her, too. Although her thesis was the first foreign study Wundt published in his psychology journal, she could not join the all-male organization of experimental psychologists founded by Titchener, her own graduate adviser (Johnson, 1997). What a different world from the recent past—1997 to 2017—when women were 10 of the 20 elected presidents of the science-oriented Association for Psychological Science. In the United States, Canada, and Europe, most psychology doctorates are now earned by women.

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

Margaret Floy Washburn (1871–1939)

The first woman to receive a psychology Ph.D., Washburn synthesized animal behavior research in *The Animal Mind* (1908).

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

William James (1842–1910) and Mary Whiton Calkins (1863–1930)

James was a legendary teacher-writer who authored an important 1890 psychology text. He mentored Calkins, who became a pioneering memory researcher and the first woman to be president of the American Psychological Association.

RETRIEVAL PRACTICE

RP-2 What event defined the start of scientific psychology?

ANSWER: Scientific psychology began in Germany in 1879 when Wilhelm Wundt opened the first psychology laboratory.

RP-3 Why did introspection fail as a method for understanding how the mind works?

ANSWER: People's self-reports varied, depending on the experience and the person's intelligence and verbal ability.

RP-4 The school of _____ used introspection to define the mind's makeup; _____ focused on how mental processes enable us to adapt, survive, and flourish.

ANSWER: structuralism; functionalism

Psychological Science Develops

LOQ **P-5** How did behaviorism, Freudian psychology, and humanistic psychology further the development of psychological science?

In psychology's early days, many psychologists shared with the English essayist C. S. Lewis the view that "there is one thing, and only one in the whole universe which we know more about than we could learn from external observation." That one thing, Lewis said, is ourselves. "We have, so to speak, inside information" (1960, pp. 18–19). Wundt and Titchener focused on inner sensations, images, and feelings. James also engaged in introspective examination of the stream of consciousness and of emotion. For these and other early pioneers, *psychology* was defined as "the science of mental life."

BEHAVIORISM That definition endured until the 1920s, when the first of two provocative American psychologists appeared on the scene. John B. Watson, and later B. F. Skinner, dismissed introspection and redefined

psychology as “the scientific study of observable behavior.” After all, they said, science is rooted in observation: What you cannot observe and measure, you cannot scientifically study. You cannot observe a sensation, a feeling, or a thought, but you *can* observe and record people’s *behavior* as they are *conditioned*—as they respond to and learn in different situations. Many agreed, and **behaviorism** was one of two major forces in psychology well into the 1960s.

behaviorism the view that psychology (1) should be an objective science that (2) studies behavior without reference to mental processes. Most psychologists today agree with (1) but not with (2).

FREUDIAN PSYCHOLOGY The other major force was *Freudian psychology*, which emphasized the ways our unconscious mind and childhood experiences affect our behavior. (In chapters to come, we’ll look more closely at Sigmund Freud’s teachings, including his theory of personality, his views on unconscious sexual conflicts, and the mind’s defenses against its own wishes and impulses.)

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

John B. Watson (1878–1958) and Rosalie Rayner (1898–1935)

Working with Rayner, Watson championed psychology as the scientific study of behavior. In a controversial study on a baby who became famous as “Little Albert,” he and Rayner showed that fear could be learned.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

B. F. Skinner (1904–1990)

This leading behaviorist rejected introspection and studied how consequences shape behavior.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Sigmund Freud (1856–1939)

The controversial ideas of this famed personality theorist and therapist

have influenced humanity's self-understanding.

HUMANISTIC PSYCHOLOGY As the behaviorists had rejected the early 1900's definition of *psychology*, other groups rejected the behaviorist definition. In the 1960s, [humanistic psychologists](#), led by Carl Rogers and Abraham Maslow, found both behaviorism and Freudian psychology too limiting. Rather than focusing on conditioned responses or childhood memories, the humanistic psychologists focused on our needs for love and acceptance and on environments that nurture or limit personal growth.

humanistic psychology historically significant perspective that emphasized human growth potential.

RETRIEVAL PRACTICE

RP-5 From the 1920s through the 1960s, the two major forces in psychology were _____ and _____ psychology.

ANSWER: behaviorism; Freudian

Contemporary Psychology

LOQ P-6 How has contemporary psychology focused on cognition, on biology and experience, on culture and gender, and on human flourishing?

Psychologists in the 1960s pioneered a *cognitive revolution*, leading the field back to its early interest in how our mind processes and retains information. [Cognitive psychology](#) today continues its scientific exploration of how we perceive, process, and remember information, and of how thinking and emotion interact in anxiety, depression, and other disorders. The marriage of cognitive psychology (the science of mind) and neuroscience (the science of brain) gave birth to [cognitive neuroscience](#). This specialty, with researchers

in many disciplines, studies the brain activity underlying mental activity.

cognitive psychology the study of mental processes, such as occur when we perceive, learn, remember, think, communicate, and solve problems.

cognitive neuroscience the interdisciplinary study of the brain activity linked with cognition (including perception, thinking, memory, and language).

Today's psychology builds on the work of many earlier scientists and schools of thought. To encompass psychology's concern with observable behavior *and* with inner thoughts and feelings, we now define **psychology** as the *science of behavior and mental processes*. Let's unpack this definition. *Behavior* is anything an organism *does*—any action we can observe and record. Yelling, smiling, blinking, sweating, talking, and questionnaire marking are all observable behaviors. *Mental processes* are the internal, subjective experiences we infer from behavior—sensations, perceptions, dreams, thoughts, beliefs, and feelings.

psychology the science of behavior and mental processes.

The key word in psychology's definition is *science*. Psychology is less a set of findings than a way of asking and answering questions. Our aim, then, is not merely to report results but also to show you how psychologists play their game. You will see how researchers evaluate conflicting opinions and ideas. And you will learn how all of us, whether scientists or simply curious people, can think smarter when experiencing and explaining the events of our lives.

Psychology has roots in many disciplines and countries. The young science of psychology developed from the more established fields of philosophy and biology. Wundt was both a philosopher and a physiologist. James was an American philosopher. Freud was an Austrian physician. Ivan Pavlov, who pioneered the study of learning, was a Russian physiologist. Jean Piaget, the last century's most influential observer of children, was a

Swiss biologist. These “Magellans of the mind,” as psychology historian Morton Hunt (1993) called them, illustrate the diversity of psychology’s origins.

Like those pioneers, today’s estimated 1+ million psychologists are citizens of many lands (Zoma & Gielen, 2015). The International Union of Psychological Science has 82 member nations, from Albania to Zimbabwe. In China, the first university psychology department was established in 1978; by 2016 there were some 270 (Zhang, 2016). Moreover, thanks to international publications, joint meetings, and the Internet, collaboration and communication cross borders more than ever. Psychology is *growing* and it is *globalizing*. The story of psychology—the subject of this book—continues to develop in many places, at many levels, with interests ranging from the study of nerve cell activity to the study of international conflicts. Contemporary psychology, shaped by many forces, is particularly influenced by our understanding of biology and experience, culture and gender, and human flourishing.

Evolutionary Psychology and Behavior Genetics

Are our human traits inherited, or do they develop through experience? This has been psychology’s biggest and most persistent issue. But the debate over the [nature–nurture issue](#) is ancient. The Greek philosopher Plato (428–348 B.C.E.) assumed that we inherit character and intelligence and that certain ideas are inborn. Aristotle (384–322 B.C.E.) countered that there is nothing in the mind that does not first come in from the external world through the senses.

nature–nurture issue the longstanding controversy over the relative contributions that genes and experience make to the development of psychological traits and behaviors. Today’s science sees traits and behaviors arising from the interaction of nature and nurture.

In the 1600s, European philosophers rekindled the debate. John Locke argued that the mind is a blank slate on which experience writes. René Descartes disagreed, believing that some ideas are innate. Descartes’ views

gained support from a curious naturalist two centuries later. In 1831, an indifferent student but ardent collector of beetles, mollusks, and shells set sail on a historic round-the-world journey. The 22-year-old voyager, Charles Darwin, pondered the incredible species variation he encountered, including tortoises on one island that differed from those on nearby islands. Darwin's 1859 *On the Origin of Species* explained this diversity by proposing the evolutionary process of **natural selection**: From among chance variations, nature selects traits that best enable an organism to survive and reproduce in a particular environment. Darwin's principle of natural selection—what philosopher Daniel Dennett (1996) has called “the single best idea anyone has ever had”—is still with us 150+ years later as biology's organizing principle. Evolution also has become an important principle for twenty-first-century psychology. This would surely have pleased Darwin, who believed his theory explained not only animal structures (such as a polar bear's white coat) but also animal behaviors (such as the emotional expressions associated with human lust and rage).

natural selection the principle that inherited traits that better enable an organism to survive and reproduce in a particular environment will (in competition with other trait variations) most likely be passed on to succeeding generations.

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

Charles Darwin (1809–1882)

Darwin argued that natural selection shapes behaviors as well as bodies.

The nature–nurture issue recurs throughout this text as today’s psychologists explore the relative contributions of biology and experience. They ask, for example, how are we humans *alike* because of our common biology and evolutionary history? That’s the focus of [evolutionary psychology](#). And how do we individually *differ* because of our differing genes and environments? That’s the focus of [behavior genetics](#).

evolutionary psychology the study of the evolution of behavior and the mind, using principles of natural selection.

behavior genetics the study of the relative power and limits of genetic and environmental influences on behavior.

We can, for example, ask: Are gender differences biologically predisposed

or socially constructed? Is children's grammar mostly innate or formed by experience? How are intelligence and personality differences influenced by heredity and by environment? Are sexual behaviors more "pushed" by inner biology or "pulled" by external incentives? Should we treat psychological disorders—depression, for example—as disorders of the brain, disorders of thought, or both?

Such debates continue. Yet over and again we will see that in contemporary science the nature–nurture tension dissolves: *Nurture works on what nature provides*. Our species is biologically endowed with an enormous capacity to learn and adapt. Moreover, every psychological event (every thought, every emotion) is simultaneously a biological event. Thus, depression can be both a brain disorder *and* a thought disorder.

rubberball/Getty Images; © Tony Freeman/PhotoEdit – All rights reserved.

A nature-made nature–nurture experiment

Identical twins (left) have the same genes. This makes them ideal participants in studies designed to shed light on hereditary and environmental influences on personality, intelligence, and other traits. Fraternal twins (right) have different genes but often share a similar environment. Twin studies provide a wealth of findings—described in later chapters—showing the importance of both nature and nurture.

RETRIEVAL PRACTICE

RP-6 How did the cognitive revolution affect the field of psychology?

ANSWER: It recaptured the field's early interest in mental processes and made them legitimate topics for scientific study.

RP-7 What is natural selection?

ANSWER: This is the process by which nature selects from chance variations the traits that best enable an organism to survive and reproduce in a particular environment.

RP-8 What is contemporary psychology's position on the nature–nurture issue?

ANSWER: Psychological events stem from the interaction of nature and nurture, rather than from either of them acting alone.

Cross-Cultural and Gender Psychology

What can we learn about people in general from psychological studies done in one time and place—often with participants from what psychologists have called the WEIRD cultures (Western, Educated, Industrialized, Rich, and Democratic [Henrich et al., 2010])? As we will see time and again, **culture**—shared ideas and behaviors that one generation passes on to the next—matters. Our culture shapes our behavior. It influences our standards of promptness and frankness, our attitudes toward premarital sex and varying body shapes, our tendency to be casual or formal, our willingness to make eye contact, our conversational distance, and much, much more. Being aware of such differences, we can restrain our assumptions that others will think and act as we do.

culture the enduring behaviors, ideas, attitudes, values, and traditions shared by a group of people and transmitted from one generation to the next.

“All people are the same; only their habits differ.”

Confucius, 551–479 B.C.E.

It is also true, however, that our shared biological heritage unites us as a universal human family. The same underlying processes guide people everywhere. Some examples:

- People diagnosed with *specific learning disorder* (formerly called dyslexia) exhibit the same brain malfunction whether they are Italian, French, or British (Paulesu et al., 2001).
- Variation in languages may impede communication across cultures. Yet all languages share deep principles of grammar, and people from opposite hemispheres can communicate with a smile or a frown.
- People in different cultures vary in feelings of loneliness (Lykes & Kemmelmeier, 2014). But across cultures, loneliness is magnified by shyness, low self-esteem, and being unmarried (Jones et al., 1985; Rokach et al., 2002).

We are each in certain respects like all others, like some others, and like no other. Studying people of all races and cultures helps us discern our similarities and our differences, our human kinship and our diversity.

You will see throughout this book that one's socially defined *gender* (as well as one's biologically defined sex) matters, too. Today's researchers report gender differences in what we dream, in how we express and detect emotions, and in our risk for alcohol use disorder, depression, and eating disorders. Gender differences fascinate us, and studying them is potentially beneficial. For example, many researchers have observed that women carry on conversations more readily to build relationships, while men talk more to give information and advice (Tannen, 2001). Understanding these differences can help us prevent conflicts and misunderstandings in everyday interactions.

Culture and kissing

Kissing crosses cultures. Yet how we do it varies. Imagine yourself kissing someone on the lips. Do you tilt your head right or left? In Western cultures, in which people read from left to right, about two-thirds of couples kiss right, as in William and Kate's famous kiss, and in Auguste Rodin's sculpture, *The Kiss*. In one study, 77 percent of Hebrew- and Arabic-language right-to-left readers kissed tilting left (Shaki, 2013).

But again, psychologically as well as biologically, women and men are overwhelmingly similar. Whether female or male, we learn to walk at about the same age. We experience the same sensations of light and sound. We remember vivid emotional events and forget mundane details. We feel the same pangs of hunger, desire, and fear. We exhibit similar overall intelligence and well-being.

The point to remember: Even when specific attitudes and behaviors vary by gender or across cultures, as they often do, the underlying processes are much the same.

Our online learning tools will help you excel in this course. Take advantage of self-tests, interactive simulations, Immersive Learning “How Would You Know?” activities, and “Assess Your Strengths” personal self-assessments. See LaunchPadWorks.com for more information.

Positive Psychology

Psychology's first hundred years often focused on understanding and treating troubles, such as abuse and anxiety, depression and disease, prejudice and poverty. Much of today's psychology continues the exploration of such challenges. Without slighting the need to repair damage and cure disease, Martin Seligman and others (2002, 2005, 2011) have called for more research on *human flourishing*. These psychologists call their approach [positive psychology](#). They believe that happiness is a by-product of a pleasant, engaged, and meaningful life. Thus, positive psychology uses scientific methods to explore the building of a “good life” that engages our skills, and a “meaningful life” that points beyond ourselves.

positive psychology the scientific study of human flourishing, with the goals of discovering and promoting strengths and virtues that help individuals and communities to thrive.

Psychology's Three Main Levels of Analysis

LOQ P-7 What are psychology's levels of analysis and related perspectives?

 For an excellent tour of psychology's roots, view the 9.5-minute **Video: The History of Psychology**.

Each of us is a complex system that is part of a larger social system. But each of us is also composed of smaller systems, such as our nervous system and body organs, which are composed of still smaller systems—cells, molecules, and atoms.

These tiered systems suggest different [levels of analysis](#), which offer complementary outlooks. It's like explaining horrific school shootings. Is it because the shooters have brain disorders or genetic tendencies that cause them to be violent? Because they have observed brutality and mayhem in the media or played violent video games? Because they live in a gun-toting society? Such perspectives are complementary because “everything is related

to everything else” (Brewer, 1996). Together, different levels of analysis form an integrated **biopsychosocial approach**, which considers the influences of biological, psychological, and social-cultural factors (**FIGURE 1**).

levels of analysis the differing complementary views, from biological to psychological to social-cultural, for analyzing any given phenomenon.

biopsychosocial approach an integrated approach that incorporates biological, psychological, and social-cultural levels of analysis.

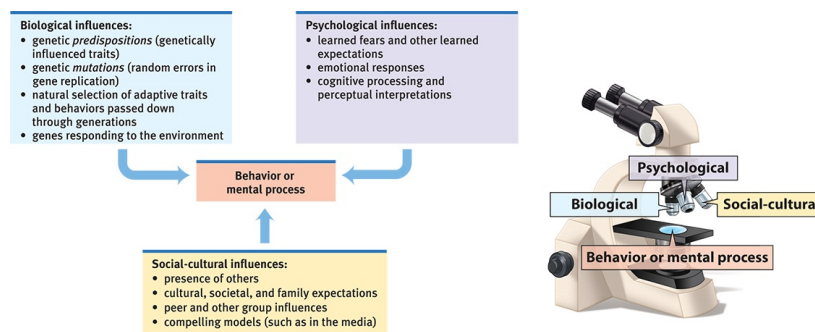

FIGURE 1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1 Biopsychosocial approach

This integrated viewpoint incorporates various levels of analysis and offers a more complete picture of any given behavior or mental process.

Each level of analysis offers a perspective for looking at a behavior or mental process, yet each by itself is incomplete. Each perspective described in **TABLE 1** asks different questions and has its limits. Together they complement one another. Consider, for example, how they shed light on anger:

- Someone working from a *neuroscience perspective* might study brain circuits that cause us to be red in the face and “hot under the collar.”
- Someone working from an *evolutionary perspective* might analyze how anger facilitated the survival of our ancestors’ genes.
- Someone working from a *behavior genetics perspective* might study how heredity and experience influence our individual differences in temperament.

- Someone working from a *psychodynamic perspective* might view an outburst as an outlet for unconscious hostility.
- Someone working from a *behavioral perspective* might attempt to determine what triggers angry responses or aggressive acts.
- Someone working from a *cognitive perspective* might study how our interpretation of a situation affects our anger and how our anger affects our thinking.
- Someone working from a *social-cultural perspective* might explore how expressions of anger vary across cultural contexts.

JUERGEN SCHWARZ/AFP/Getty Images

TABLE 1.1

Psychology's Current Perspectives

Perspective	Focus	Sample Questions	Examples of Subfields Using This Perspective
<i>Neuroscience</i>	How the body and brain enable emotions, memories, and sensory experiences	How do pain messages travel from the hand to the brain? How is blood chemistry linked with moods and motives?	Biological; cognitive; clinical
<i>Evolutionary</i>	How the	How does evolution	Biological;

	natural selection of traits has promoted the survival of genes	influence behavior tendencies?	developmental; social
<i>Behavior genetics</i>	How our genes and our environment influence our individual differences	To what extent are psychological traits such as intelligence, personality, sexual orientation, and vulnerability to depression products of our genes? Of our environment?	Personality; developmental; legal/forensic
<i>Psychodynamic</i>	How behavior springs from unconscious drives and conflicts	How can someone's personality traits and disorders be explained by unfulfilled wishes and childhood traumas?	Clinical; counseling; personality
<i>Behavioral</i>	How we learn observable responses	How do we learn to fear particular objects or situations? What is the most effective way to alter our behavior, say, to lose weight or stop smoking?	Clinical; counseling; industrial-organizational
<i>Cognitive</i>	How we encode, process, store, and retrieve	How do we use information in remembering? Reasoning? Solving problems?	Cognitive neuroscience; clinical; counseling; industrial-

	information		organizational
<i>Social-cultural</i>	How behavior and thinking vary across situations and cultures	How are we affected by the people around us, and by our surrounding culture?	Developmental; social; clinical; counseling

The point to remember: Like two-dimensional views of a three-dimensional object, each of psychology's perspectives is helpful. But each by itself fails to reveal the whole picture.

RETRIEVAL PRACTICE

RP-9 What advantage do we gain by using the biopsychosocial approach in studying psychological events?

ANSWER: By incorporating three different levels of analysis, the biopsychosocial approach can provide a more complete view than any one perspective could offer.

RP-10 The _____ - _____ perspective in psychology focuses on how behavior and thought differ from situation to situation and from culture to culture, while the _____ perspective emphasizes observation of how we respond to and learn in different situations.

ANSWER: social-cultural; behavioral

Psychology's Subfields

LOQ **P-8** What are psychology's main subfields?

Picturing a chemist at work, you may envision a laboratory scientist surrounded by test tubes and high-tech equipment. Picture a psychologist at work and you would be right to envision

- a white-coated scientist probing a rat's brain.
- an intelligence researcher measuring how quickly an infant shows boredom by looking away from a familiar picture.
- an executive evaluating a new “healthy lifestyles” training program for employees.
- a researcher at a computer analyzing “big data” from Twitter or Facebook status updates.
- a therapist actively listening to a depressed client's thoughts.
- a traveling academic visiting another culture and collecting data on variations in human values and behaviors.
- a teacher or writer sharing the joy of psychology with others.

The cluster of subfields we call psychology is a meeting ground for different disciplines. “Psychology is a hub scientific discipline,” said Association for Psychological Science past-president John Cacioppo (2007). Thus, it's a perfect home for those with wide-ranging interests. In its diverse activities, from biological experimentation to cultural comparisons, the tribe of psychology is united by a common quest: *describing and explaining behavior and the mind underlying it.*

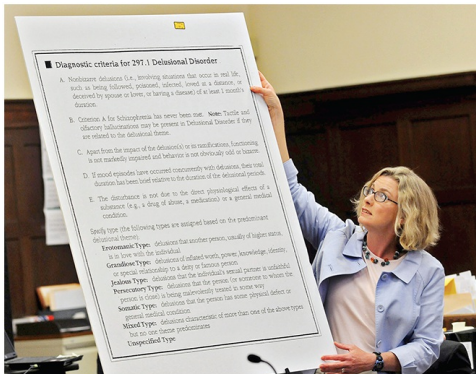

The New Yorker Collection, 1986, J.B. Handelsman from cartoonbank.com

“I’m a social scientist, Michael. That means I can’t explain electricity or anything like that, but if you ever want to know about

people I'm your man."

Some psychologists conduct **basic research** that builds psychology's knowledge base. We will meet a wide variety of such researchers, including *biological psychologists* exploring the links between body and mind; *developmental psychologists* studying our changing abilities from womb to tomb; *cognitive psychologists* experimenting with how we perceive, think, and solve problems; *personality psychologists* investigating our persistent traits; and *social psychologists* exploring how we view and affect one another.

basic research pure science that aims to increase the scientific knowledge base.

Ted Fitzgerald/AP Images; Image Source/Getty Images

Psychology in court

Forensic psychologists apply psychology's principles and methods in the criminal justice system. They may assess witness credibility or testify in court on a defendant's state of mind and future risk.

These and other psychologists also may conduct **applied research**, tackling practical problems. *Industrial-organizational psychologists*, for example, use psychology's concepts and methods in the workplace to help organizations and companies select and train employees, boost morale and productivity, design products, and implement systems.

applied research scientific study that aims to solve practical problems.

Psychology is a science, but also a profession that helps people have healthier relationships, overcome anxiety or depression, and raise thriving children. [Counseling psychologists](#) help people to cope with challenges and crises (including academic, vocational, and relationship issues) and to improve their personal and social functioning. [Clinical psychologists](#) assess and treat people with mental, emotional, and behavior disorders. Both counseling and clinical psychologists administer and interpret tests, provide counseling and therapy, and sometimes conduct basic and applied research. By contrast, [psychiatrists](#), who also may provide psychotherapy, are medical doctors licensed to prescribe drugs and otherwise treat physical causes of psychological disorders.

counseling psychology a branch of psychology that assists people with problems in living (often related to school, work, or marriage) and in achieving greater well-being.

clinical psychology a branch of psychology that studies, assesses, and treats people with psychological disorders.

psychiatry a branch of medicine dealing with psychological disorders; practiced by physicians who are licensed to provide medical (for example, drug) treatments as well as psychological therapy.

Rather than seeking to change people to fit their environment, [community psychologists](#) work to create social and physical environments that are healthy for all (Bradshaw et al., 2009; Trickett, 2009). To prevent bullying, they might consider ways to improve the culture of the school and neighborhood, and how to increase bystander intervention (Polanin et al., 2012).

community psychology a branch of psychology that studies how people interact with their social environments and how social institutions affect individuals and groups.

With perspectives ranging from the biological to the social, and with settings ranging from the laboratory to the clinic to the office, psychology relates to many fields. Psychologists teach in medical schools, business schools, law schools, and theological seminaries, and they work in hospitals, factories, and corporate offices. They engage in interdisciplinary studies, such as psychohistory (the study of people’s historical motivations), psycholinguistics (the study of language and thinking), and psychoceramics (the study of crackpots).¹

Psychology: A science and a profession

Psychologists experiment with, observe, test, and help modify behavior. Here we see psychologists testing a child, measuring emotion-related physiology, and doing face-to-face therapy.

Want to learn more? See Appendix B, Career Fields in Psychology, at the end of this book, and go to the online ***Pursuing a Psychology Career*** resource to learn about the many interesting options available to those with bachelor’s, master’s, and doctoral degrees in psychology. To review and test your understanding of psychology’s perspectives and subfields, engage online with **Concept Practice: Psychology’s Current Perspectives** and **Concept Practice: Psychology’s Subfields**.

“Once expanded to the dimensions of a larger idea, [the mind] never returns to its original size.”

Oliver Wendell Holmes, 1809–1894

Psychology also influences modern culture. Knowledge transforms us. Learning about the solar system and the germ theory of disease alters the way people think and act. Learning about psychology’s findings also changes

people: They less often judge psychological disorders as moral failings, treatable by punishment and ostracism. They less often regard and treat women as men's mental inferiors. They less often view and raise children as ignorant, willful beasts in need of taming. "In each case," noted Morton Hunt (1990, [p. 206](#)), "knowledge has modified attitudes, and, through them, behavior." Once aware of psychology's well-researched ideas—about how body and mind connect, how a child's mind grows, how we construct our perceptions, how we learn and remember, how people across the world are alike (and different)—your mind may never again be quite the same.

But bear in mind psychology's limits. Don't expect it to answer the ultimate questions, such as those posed by Russian novelist Leo Tolstoy (1904): "Why should I live? Why should I do anything? Is there in life any purpose which the inevitable death that awaits me does not undo and destroy?"

Although many of life's significant questions are beyond psychology, some very important ones are illuminated by even a first psychology course. Through painstaking research, psychologists have gained insights into brain and mind, dreams and memories, depression and joy. Even the unanswered questions can renew our sense of mystery about things we do not yet understand. Moreover, your study of psychology can help teach you how to ask and answer important questions—how to think critically as you evaluate competing ideas and claims.

"I have uttered what I did not understand, things too wonderful for me."

Job 42:3

Psychology deepens our appreciation for how we humans perceive, think, feel, and act. By so doing it can enrich our lives and enlarge our vision. Through this book we hope to help guide you toward that end. As educator Charles Eliot said a century ago: "Books are the quietest and most constant of friends, and the most patient of teachers."

RETRIEVAL PRACTICE

RP-11 Match the specialty on the left with the description on the right.

1. Clinical psychology
2. Psychiatry
3. Community psychology
 - a. Works to create social and physical environments that are healthy for all.
 - b. Studies, assesses, and treats people with psychological disorders but usually does not provide medical therapy.
 - c. Branch of medicine dealing with psychological disorders.

ANSWER: 1. b, 2. c, 3. a

Use Psychology to Become a Stronger Person—and a Better Student

LOQ P-9 How can psychological principles help you learn, remember, and thrive?

Throughout this text, we will offer evidence-based suggestions that you can use to live a happy, effective, flourishing life, including the following:

- *Get a full night's sleep.* Unlike sleep-deprived people, who live with fatigue and gloomy moods, well-rested people live with greater energy, alertness, and productivity.
- *Make space for exercise.* Aerobic activity not only increases health and energy, it also is an effective remedy for mild to moderate depression and anxiety.
- *Set long-term goals, with daily aims.* Successful people take time each day to work toward their goals, such as exercising, sleeping more, or eating more healthfully. Over time, they often find that their daily practice becomes a habit.
- *Have a “growth mindset.”* Rather than seeing their abilities as fixed, successful people view their mental abilities as like a muscle—something that grows stronger with effortful use.
- *Prioritize relationships.* We humans are social animals. We flourish when

connected in close relationships. We are both happier and healthier when supported by (and supporting) caring friends.

Psychology's research also shows how we can learn and retain information. Many students assume that the way to cement new learning is to reread. What helps even more—and what this book therefore encourages—is repeated self-testing and rehearsal of previously studied material. Memory researchers Henry Roediger and Jeffrey Karpicke (2006) call this phenomenon the [testing effect](#). (It is also sometimes called the *retrieval practice effect* or *test-enhanced learning*.) They note that “testing is a powerful means of improving learning, not just assessing it.” In one of their studies, English-speaking students recalled the meaning of 40 previously learned Swahili words much better if tested repeatedly than if they spent the same time restudying the words (Karpicke & Roediger, 2008). Many other studies, including in college classrooms, confirm that *frequent quizzing and self-testing boosts students' retention* (McDaniel et al., 2015; Trumbo et al., 2016).

testing effect enhanced memory after retrieving, rather than simply rereading, information. Also referred to as a *retrieval practice effect* or *test-enhanced learning*.

“If you read a piece of text through twenty times, you will not learn it by heart so easily as if you read it ten times while attempting to recite it from time to time and consulting the text when your memory fails.”

Francis Bacon, *Novum Organum*, 1620

As you will see in [Chapter 8](#), to master information you must *actively process it*. Your mind is not like your stomach, something to be filled passively; it grows stronger only with effort. Countless experiments reveal that people learn and remember best when they put material in their own words, rehearse it, and then retrieve and review it again.

The [SQ3R](#) study method incorporates these principles (McDaniel et al., 2009; Robinson, 1970). SQ3R is an acronym for its five steps: Survey,

Question, Read, Retrieve,² Review.

SQ3R a study method incorporating five steps: Survey, Question, Read, Retrieve, Review.

To study a chapter, first *survey*, taking a bird's-eye view. Scan the table of contents on the chapter's first page, and notice the organization.

Before you read each main section, try to answer its numbered Learning Objective *Question* (for this section: "How can psychological principles help you learn, remember, and thrive?"). Roediger and Bridgid Finn (2010) have found that "trying and failing to retrieve the answer is actually helpful to learning." Those who test their understanding *before* reading, and discover what they don't yet know, will learn and remember better.

Then *read*, actively searching for the answer to the question. At each sitting, read only as much of the chapter (usually a single main section) as you can absorb without tiring. Read actively and critically. Ask questions. Take notes. Make the ideas your own: How does what you've read relate to your own life? Does it support or challenge your assumptions? How convincing is the evidence?

Having read a section, *retrieve* its main ideas: "Active retrieval promotes meaningful learning," says Karpicke (2012). So *test yourself*. This will not only help you figure out what you know, the testing itself will help you learn and retain the information more effectively. Even better, test yourself repeatedly. To facilitate this, we offer periodic *Retrieval Practice* opportunities throughout each chapter (see, for example, the questions at the end of this section). After answering these questions for yourself, you can check the answers provided, and reread as needed.

"It pays better to wait and recollect by an effort from within, than to look at the book again."

William James, *Principles of Psychology*, 1890

Finally, *review*: Read over any notes you have taken, again with an eye on

the chapter's organization, and quickly review the whole chapter. Write or say what a concept is before rereading to check your understanding.

Survey, question, read, retrieve, review. We have organized this book's chapters to facilitate your use of the SQ3R study system. Each chapter begins with an outline that aids your *survey*. Headings and Learning Objective *Questions* suggest issues and concepts you should consider as you *read*. The material is organized into sections of readable length. The Retrieval Practice questions will challenge you to *retrieve* what you have learned, and thus better remember it. The end-of-section *Review* is set up as a self-test, with the collected Learning Objective Questions and key terms listed, along with Master the Material questions in a variety of formats. In the e-book, answer-checking is a click away. In the printed text, answers may be found in [Appendix C](#) and Appendix D. Survey, question, read . . .

Four additional study tips may further boost your learning:

Distribute your study time. One of psychology's oldest findings is that *spaced practice* promotes better retention than *massed practice*. You'll remember material better if you space your time over several study periods—perhaps one hour a day, six days a week—rather than cram it into one week-long or all-night study blitz. For example, rather than trying to read an entire chapter in a single sitting, read just one main section and then turn to something else. *Interleaving* your study of psychology with your study of other subjects boosts long-term retention and protects against overconfidence (Kornell & Bjork, 2008; Taylor & Rohrer, 2010).

Spacing your study sessions requires a disciplined approach to managing your time. At the beginning of this text, Richard O. Straub explains time management in a helpful preface.

Learn to think critically. Whether you are reading or in class, note people's assumptions and values. What perspective or bias underlies an argument? Evaluate evidence. Is it anecdotal? Or is it based on informative experiments? Assess conclusions. Are there alternative explanations?

Process class information actively. Listen for the main ideas and sub-ideas of a lecture. *Write them down*. Ask questions during and after class. In class, as in your private study, process the information actively and you will understand and retain it better. As psychologist William James urged a century ago, “*No reception without reaction, no impression without . . . expression.*” Make the information your own. Relate what you read to what

you already know. Tell someone else about it. (As any teacher will confirm, to teach is to remember.)

Also, take notes *by hand*. Handwritten notes, in your own words, typically engage more active processing, with better retention, than does verbatim note-taking on laptops (Mueller & Oppenheimer, 2014).

Overlearn. Psychology tells us that overlearning improves retention. We are prone to overestimating how much we know. You may understand a chapter as you read it, but that feeling of familiarity can be deceptively comforting. By using the Retrieval Practice questions as well as our online learning opportunities, you can test your knowledge and *overlearn* in the process.

Memory experts Elizabeth Bjork and Robert Bjork (2011) offer the bottom line for how to improve your retention and your grades:

Spend less time on the input side and more time on the output side, such as summarizing what you have read from memory or getting together with friends and asking each other questions. Any activities that involve testing yourself—that is, activities that require you to retrieve or generate information, rather than just representing information to yourself—will make your learning both more durable and flexible. ([p. 63](#))

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

How can critical thinking help you evaluate claims in the media, even if you're not a scientific expert on the issue?

In 1879, in psychology's first experiment, _____ and his students measured the time lag between hearing a ball hit a platform and pressing a key.

William James would be considered a(n) _____. Wilhelm Wundt and Edward Titchener would be considered _____.

- a. functionalist; structuralists
- b. structuralist; functionalists
- c. evolutionary theorist; structuralists
- d. functionalist; evolutionary theorists

In the early twentieth century, _____ redefined psychology as "the science of observable behavior."

- a. John B. Watson
- b. Abraham Maslow
- c. William James
- d. Sigmund Freud

Nature is to nurture as

- a. personality is to intelligence.
- b. biology is to experience.
- c. intelligence is to biology.
- d. psychological traits are to behaviors.

"Nurture works on what nature provides." Describe what this means, using your own words.

Which of the following is true regarding gender differences and similarities?

- a. Differences between the genders outweigh any similarities.
- b. Despite some gender differences, the underlying processes of human behavior are the same.
- c. Both similarities and differences between the genders depend more on biology than on environment.
- d. Gender differences are so numerous that it is difficult to make meaningful comparisons.

Martin Seligman and other researchers who explore various aspects of human flourishing refer to their field of study as _____.

A psychologist treating emotionally troubled adolescents at a local mental health agency is most likely to be a(n)

- a. research psychologist.
- b. psychiatrist.
- c. industrial-organizational psychologist.
- d. clinical psychologist.

A mental health professional with a medical degree who can prescribe medication is a _____.

A psychologist conducting basic research to expand psychology's knowledge base may

- a. design a computer screen with limited glare and assess the effect on computer operators' eyes after a day's work.
- b. treat older people who are overcome by depression.
- c. observe 3- and 6-year-olds solving puzzles and analyze differences in their abilities.
- d. interview children with behavioral problems and suggest treatments.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Significant Differences

Hoping to satisfy their curiosity about people and to relieve their own woes, millions turn to “psychology.” They watch television shows aimed at helping people cope with their problems, overcome their addictions, and save their marriages. They read articles on supposed psychic powers. They attend stop-smoking hypnosis seminars. They play online games hoping to strengthen their brain. They immerse themselves in self-help websites and books on the meaning of dreams, the path to ecstatic love, and the road to personal happiness.

Others, intrigued by claims of psychological truth, wonder: How—and how much—does parenting shape children’s personalities and abilities? Are first-born children more driven to achieve? Do dreams have deep meaning? Do we sometimes remember events that never happened? Does psychotherapy heal?

In working with such questions, how can we separate uninformed opinions from examined conclusions? Let’s consider how psychology’s researchers put the scientific method into action to learn more about this fascinating field.

Research Strategies: How Psychologists Ask and Answer Questions

The Need for Psychological Science

LOQ **LEARNING OBJECTIVE QUESTION** **1-1** How does our everyday thinking sometimes lead us to a wrong conclusion?

Some people suppose that psychology is mere common sense—documenting and dressing in jargon what people already know: “You get paid for using fancy methods to prove what my grandmother knows?” Indeed, Grandma is often right. As the baseball great Yogi Berra (1925–2015) once said, “You can observe a lot by watching.” (We have Berra to thank for other gems, such as “Nobody goes there any more—it’s too crowded,” and “If the people don’t want to come out to the ballpark, nobody’s gonna stop ’em.”) Because we’re all behavior watchers, it would be surprising if many of psychology’s findings had *not* been foreseen. Many people believe that love breeds happiness, for example, and they are right (we have what [Chapter 11](#) calls a deep “need to belong”).

But sometimes Grandma’s common sense, informed by countless casual observations, is wrong. In later chapters, we will see how research has overturned popular ideas—that familiarity breeds contempt, that dreams predict the future, and that most of us use only 10 percent of our brain. We will also see how research has surprised us with discoveries about how the brain’s chemical messengers control our moods and memories, about other animals’ abilities, and about the effects of stress on our capacity to fight disease.

Other things seem like commonsense truth only because we so often hear them repeated. Mere repetition of statements—whether true or false—makes them easier to process and remember, and thus more true-seeming (Dechêne et al., 2010; Fazio et al., 2015). Easy to remember misconceptions (“Vitamin

C prevents the common cold”) can therefore overwhelm hard truths. This power of familiar, hard-to-erase falsehoods is a lesson well known to political manipulators, and kept in mind by critical thinkers.

Three roadblocks to critical thinking—*hindsight bias*, *overconfidence*, and *perceiving patterns in random events*—help illustrate why we cannot rely solely on common sense.

“Those who trust in their own wits are fools.”

Proverbs 28:26

Did We Know It All Along? Hindsight Bias

Consider how easy it is to draw the bull’s eye *after* the arrow strikes. After the stock market drops, people say it was “due for a correction.” After the athletic match, we credit the coach if a “gutsy play” wins the game, and fault the coach for the same “stupid play” if it doesn’t. After a war or an election, its outcome usually seems obvious. Although history may therefore seem like a series of inevitable events, the actual future is seldom foreseen. No one’s diary recorded, “Today the Hundred Years War began.”

“Life is lived forwards, but understood backwards.”

Philosopher Søren Kierkegaard, 1813–1855

This [hindsight bias](#) (also known as the *I-knew-it-all-along phenomenon*) is easy to demonstrate by giving half the members of a group some purported psychological finding, and giving the other half an opposite result. Tell the first group, for example: “Psychologists have found that separation weakens romantic attraction. As the saying goes, ‘Out of sight, out of mind.’” Ask them to imagine why this might be true. Most people can, and after explaining it nearly all will then view this true finding as unsurprising.

hindsight bias the tendency to believe, after learning an outcome, that one would have foreseen it. (Also known as the *I-knew-it-all-along phenomenon*.)

Tell the second group the opposite: “Psychologists have found that separation strengthens romantic attraction. As the saying goes, ‘Absence makes the heart grow fonder.’” People given this untrue result can also easily imagine it, and most will also see it as unsurprising. When opposite findings both seem like common sense, there is a problem.

“Anything seems commonplace, once explained.”

Dr. Watson to Sherlock Holmes

Such errors in people’s recollections and explanations show why we need psychological research. It’s not that common sense is usually wrong. Rather, common sense describes, after the fact, what *has* happened better than it predicts what *will* happen.

More than 800 scholarly papers have shown hindsight bias in people young and old from across the world (Roese & Vohs, 2012). As physicist Niels Bohr reportedly jested, “Prediction is very difficult, especially about the future.”

U.S. Coast Guard/Handout/Everett Collection/Newscom

Hindsight bias

When drilling its Deepwater Horizon oil well in 2010, BP employees took

shortcuts and ignored warning signs, without intending to harm any people, the environment, or their company's reputation. After the resulting Gulf oil spill, with the benefit of hindsight, the foolishness of those judgments became obvious.

Overconfidence

We humans tend to think we know more than we do. Asked how sure we are of our answers to factual questions (*Is Boston north or south of Paris?*), we tend to be more confident than correct.¹ Or consider these three anagram solutions (from Goranson, 1978):

WREAT —> WATER

ETRYN —> ENTRY

GRABE —> BARGE

About how many seconds do you think it would have taken you to unscramble each of these? Did hindsight influence you? Knowing the answers tends to make us overconfident. (Surely the solution would take only 10 seconds or so?) In reality, the average problem solver spends 3 minutes, as you also might, given a similar anagram without the solution: OCHSA.²

Fun anagram solutions from Wordsmith (wordsmith.org): Snooze alarms = Alas! No more z's
Dormitory = dirty room
Slot machines = cash lost in 'em

Are we any better at predicting social behavior? Psychologist Philip Tetlock (1998, 2005) collected more than 27,000 expert predictions of world events, such as the future of South Africa or whether Quebec would separate from Canada. His repeated finding: These predictions, which experts made with 80 percent confidence on average, were right less than 40 percent of the time. Nevertheless, even those who erred maintained their confidence by noting they were “almost right.” “The Québécois separatists *almost* won the secessionist referendum.”

Overconfidence in history: “We don’t like their sound. Groups of

guitars are on their way out.”

Decca Records, in turning down a recording contract with the Beatles in 1962

“Computers in the future may weigh no more than 1.5 tons.”

Popular Mechanics, 1949

RETRIEVAL PRACTICE

RP-1 Why, after friends start dating, do we often feel that we *knew* they were meant to be together?

ANSWER: We often suffer from hindsight bias—after we’ve learned a situation’s outcome, that outcome seems familiar and therefore obvious.

Perceiving Order in Random Events

For most people, a random, unpredictable world is unsettling (Tullett et al., 2015). We therefore have a built-in eagerness to make sense of our world. People may see a face on the Moon, hear satanic messages in music, perceive the Virgin Mary’s image on a grilled cheese sandwich. Even in random data, we often find patterns, because—here’s a curious fact of life—*random sequences often don’t look random* (Falk et al., 2009; Nickerson, 2002, 2005). Flip a coin 50 times and you will likely be surprised at the streaks of heads or tails—much like supposed “hot” and “cold” streaks in basketball shooting and baseball hitting. In actual random sequences, patterns and streaks (such as repeating digits) occur more often than people expect (Oskarsson et al., 2009). That also makes it hard for people to generate random-like sequences. When embezzlers try to simulate random digits, their nonrandom patterns can alert fraud experts (Poundstone, 2014).

“They couldn’t hit an elephant at this distance.”

General John Sedgwick just before being killed during a U.S. Civil War

“The telephone may be appropriate for our American cousins, but not here, because we have an adequate supply of messenger boys.”

British expert group evaluating the invention of the telephone

Some happenings, such as winning a lottery twice, seem so extraordinary that we find it difficult to conceive an ordinary, chance-related explanation. “But with a large enough sample, any outrageous thing is likely to happen,” note statisticians Persi Diaconis and Frederick Mosteller (1989). An event that happens to but 1 in 1 billion people every day occurs about 7 times a day, more than 2500 times a year.

BIZARRE SEQUENCE OF COMPUTER-GENERATED
RANDOM NUMBERS

*Bizarre-looking, perhaps. But actually
no more unlikely than any other number
sequence.*

© 1990 by Sidney Harris/
American Scientist magazine.

The point to remember: Hindsight bias, overconfidence, and our tendency to perceive patterns in random events tempt us to overestimate our intuition. But scientific inquiry can help us sift reality from illusion.

“The really unusual day would be one where nothing unusual happens.”

Statistician Persi Diaconis (2002)

Consider how scientific inquiry can help you think smarter about random hot streaks in sports by engaging online with **Immersive Learning: How Would You Know If There Is a “Hot Hand” in Basketball?**

The Scientific Method

At the foundation of all science is a scientific attitude that combines *curiosity*, *skepticism*, and *humility*. Psychologists arm their scientific attitude with the *scientific method*—a self-correcting process for evaluating ideas with observation and analysis. Psychological science welcomes hunches and plausible-sounding theories. And it puts them to the test. If a theory works—if the data support its predictions—so much the better for that theory. If its predictions fail, the theory gets revised or rejected.

Constructing Theories

LOQ 1-2 How do theories advance psychological science?

In everyday conversation, we often use *theory* to mean “mere hunch.” Someone might, for example, discount evolution as “only a theory”—as if it were mere speculation. In science, a **theory** explains behaviors or events by offering ideas that organize observations. By using deeper principles to organize isolated facts, a theory summarizes and simplifies. As we connect the observed dots, a coherent picture emerges.

theory an explanation using an integrated set of principles that organizes observations and predicts behaviors or events.

A theory of how sleep affects memory, for example, helps us organize countless sleep-related observations into a short list of principles. Imagine

that we observe over and over that people with good sleep habits tend to answer questions correctly in class and do well at test time. We might therefore theorize that sleep improves memory. So far so good: Our principle neatly summarizes a list of observations about the effects of a good night's sleep.

Yet no matter how reasonable a theory may sound—and it does seem reasonable to suggest that sleep boosts memory—we must put it to the test. A good theory produces testable *predictions*, called **hypotheses**. Such predictions specify what results would support the theory and what results would disconfirm it. To test our theory about sleep effects on memory, our hypothesis might be that when sleep deprived, people will remember less from the day before. To test that hypothesis, we might assess how well people remember course materials they studied either before a good night's sleep or before a shortened night's sleep (**FIGURE 1.1**). The results will either support our theory or lead us to revise or reject it.

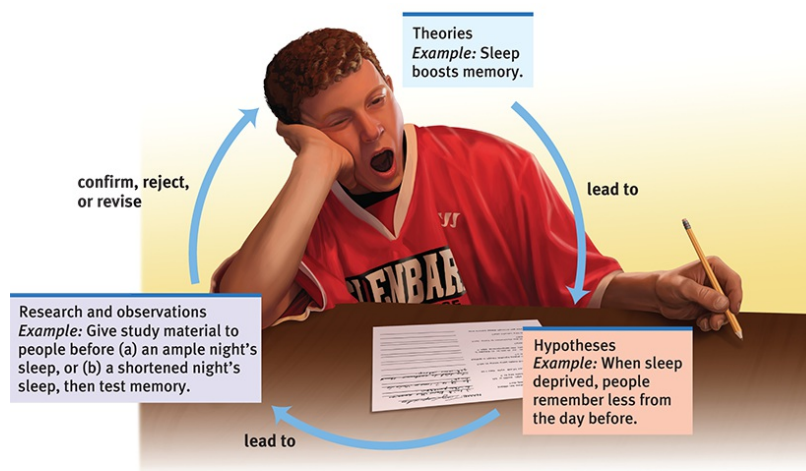

FIGURE 1.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1.1 The scientific method

A self-correcting process for asking questions and observing nature's answers.

hypothesis a testable prediction, often implied by a theory.

Our theories can bias our observations. Having theorized that better memory springs from more sleep, we may see what we expect: We may perceive sleepy people's comments as less accurate. The urge to see what we expect is ever-present, both inside and outside the laboratory, as when people's views of climate change influence their interpretation of local weather events.

As a check on their biases, psychologists report their research with precise **operational definitions** of procedures and concepts. *Sleep deprived*, for example, may be defined as "X hours less" than the person's natural sleep. Using these carefully worded statements, others can **replicate** (repeat) the original observations with different participants, materials, and circumstances. If they get similar results, confidence in the finding's reliability grows. The first study of hindsight bias, for example, aroused psychologists' curiosity. Now, after many successful replications with differing people and questions, we feel sure of the phenomenon's power. Replication is confirmation.

operational definition a carefully worded statement of the exact procedures (operations) used in a research study. For example, *human intelligence* may be operationally defined as what an intelligence test measures.

replication repeating the essence of a research study, usually with different participants in different situations, to see whether the basic finding can be reproduced.

Replication is an essential part of good science. In psychology, recent replication efforts have produced mixed results. One recent cluster of replications brought encouraging news: All but 2 of 13 experiments were successfully replicated (Klein et al., 2014). But then when 270 psychologists together redid 100 psychological studies, the results were disheartening: Only 36 percent of the results were replicated (Open Science Collaboration, 2015). (None of the nonreproducible findings appears in this text.) However, another team of scientists found that most of the failed replications did not accurately re-create the original study. "The reproducibility of psychological science" is actually "quite high," they concluded (Gilbert et al., 2016). Still others argued that certain research topics made replication more difficult (Van Bavel et al.,

2016). Despite the differing findings, most researchers agree that science will benefit from more replications and from greater transparency as researchers increasingly disclose their detailed methods and data (Munafò et al., 2017; Open Science Collaboration, 2017).

Other fields, including medicine, also have nonreplicated findings (Collins & Tabak, 2014). Especially when based on a small sample, a single failure to replicate needs replication itself (Maxwell et al., 2015). In all scientific fields, replication either confirms findings, or enables us to revise our understanding.

“Failure to replicate is not a bug; it is a feature. It is what leads us along the path—the wonderfully twisty path—of scientific discovery.”

Lisa Feldman Barrett, “Psychology Is Not in Crisis,” 2015

In both psychological and medical science, another important tool in psychology’s toolkit is *meta-analysis*. A meta-analysis statistically combines the results of many studies to provide a bottom-line result.

In the end, our theory will be useful if it (1) *organizes* observations, and (2) implies *predictions* that anyone can use to check the theory or to derive practical applications. (Does people’s sleep predict their retention?) Eventually, our research may (3) stimulate further research that leads to a revised theory that better organizes and predicts.

As we will see next, we can test our hypotheses and refine our theories using *descriptive* methods (which describe behaviors, often through case studies, surveys, or naturalistic observations), *correlational* methods (which associate different factors), and *experimental* methods (which manipulate factors to discover their effects). To think critically about popular psychology claims, we need to understand these methods and know what conclusions they allow.

RETRIEVAL PRACTICE

RP-2 What does a good theory do?

ANSWER: 1. It *organizes* observed facts. 2. It implies hypotheses that offer testable *predictions* and, sometimes, practical

applications. 3. It often stimulates further research.

RP-3 Why is replication important?

ANSWER: When other investigators are able to replicate an experiment with the same (or stronger) results, scientists can confirm the result and become more confident of its reliability.

Description

LOQ 1-3 How do psychologists use case studies, naturalistic observations, and surveys to observe and describe behavior, and why is random sampling important?

The starting point of any science is description. In everyday life, we all observe and describe people, often drawing conclusions about why they think, feel, and act as they do. Professional psychologists do much the same, though more objectively and systematically, through

- *case studies* (in-depth analyses of individuals or groups).
- *naturalistic observations* (recording the natural behavior of many individuals).
- *surveys* and interviews (asking people questions).

THE CASE STUDY Among the oldest research methods, the [case study](#) examines one individual or group in depth in the hope of revealing things true of us all. Some examples:

- *Brain damage*. Much of our early knowledge about the brain came from case studies of individuals who suffered particular impairments after damage to a certain brain region.
 - *Children's minds*. Jean Piaget taught us about children's thinking after carefully observing and questioning only a few children.
 - *Animal intelligence*. Studies of various animals, including only a few chimpanzees, have revealed their capacity for understanding and language.
-

case study a descriptive technique in which one individual or group is studied in depth in the hope of revealing universal principles.

Intensive case studies are sometimes very revealing, and they often suggest directions for further study.

“‘Well my dear,’ said Miss Marple, ‘human nature is very much the same everywhere, and of course, one has opportunities of observing it at closer quarters in a village’.”

Agatha Christie, *The Tuesday Club Murders*, 1933

See the **Video: Case Studies** for an animated tutorial.

But atypical individual cases may mislead us. Both in our everyday lives and in science, unrepresentative information can lead to mistaken judgments and false conclusions. Indeed, anytime a researcher mentions a finding (*Smokers die younger: 95 percent of men over 85 are nonsmokers*) someone is sure to offer a contradictory anecdote (*Well, I have an uncle who smoked two packs a day and lived to be 89*). Dramatic stories and personal experiences (even psychological case examples) command our attention and are easily remembered. Journalists understand that, and often begin their articles with compelling stories. Stories move us. But stories can mislead. Which of the following do you find more memorable? (1) “In one study of 1300 dream reports concerning a kidnapped child, only 5 percent correctly envisioned the child as dead” (Murray & Wheeler, 1937). (2) “I know a man who dreamed his sister was in a car accident, and two days later she died in a head-on collision!” Numbers can be numbing, *but the plural of anecdote is not evidence*. A single story of someone who supposedly changed from gay to straight is not evidence that sexual orientation is a choice. As psychologist Gordon Allport (1954, [p. 9](#)) said, “Given a thimbleful of [dramatic] facts we rush to make generalizations as large as a tub.”

The point to remember: Individual cases can suggest fruitful ideas. What’s true of all of us can be glimpsed in any one of us. To find those general truths, we must employ other research methods.

RETRIEVAL PRACTICE

RP-4 We cannot assume that case studies always reveal general principles that apply to all of us. Why not?

ANSWER: Case studies involve only one individual or group, so we can't know for sure whether the principles observed would apply to a larger population.

NATURALISTIC OBSERVATION A second descriptive method records behavior in natural environments. These [naturalistic observations](#) range from watching chimpanzee societies in the jungle, to videotaping and analyzing parent-child interactions in different cultures, to recording racial differences in students' self-seating patterns in a school lunchroom.

naturalistic observation a descriptive technique of observing and recording behavior in naturally occurring situations without trying to manipulate and control the situation.

Skye Hohmann/Alamy

Freud and Little Hans

Sigmund Freud's case study of 5-year-old Hans' extreme fear of horses led Freud to his theory of childhood sexuality. He conjectured that Hans felt unconscious desire for his mother, feared castration by his rival father, and then transferred this fear into his phobia about being bitten

by a horse. As [Chapter 14](#) will explain, today's psychological science discounts Freud's theory of childhood sexuality but does agree that much of the human mind operates outside our conscious awareness.

Naturalistic observation has mostly been “small science”—science that can be done with pen and paper rather than fancy equipment and a big budget (Provine, 2012). But new technologies, such as smart-phone apps, body-worn sensors, and social media, are enabling “big data” observations. Using such tools, researchers can track people's location, activities, and opinions—without interference. The billions of people on Facebook, Twitter, and Google have also created a huge new opportunity for big-data naturalistic observation. One research team studied the ups and downs of human moods by counting positive and negative words in 504 million Twitter messages from 84 countries (Golder & Macy, 2011). As [FIGURE 1.2](#) shows, people seem happier on weekends, shortly after waking, and in the evenings. (Are late Saturday evenings often a happy time for you, too?) Another study found that the proportion of negative emotion (especially anger-related) words in 148 million tweets from 1347 U.S. counties predicted the counties' heart disease rates. Moreover, it did so even better than other predictors such as smoking and obesity rates (Eichstaedt et al., 2015).

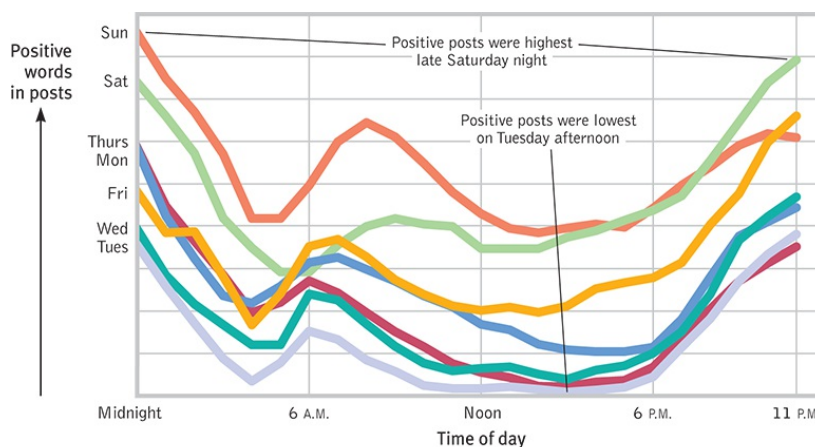

FIGURE 1.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Golder & Macy, 2011.

FIGURE 1.2 Twitter message moods, by time and by day

This illustrates how, without knowing anyone's identity, big data enable researchers to study human behavior on a massive scale. It now is also possible to associate people's moods with, for example, their locations or with the weather, and to study the spread of ideas through social networks.

Like the case study, naturalistic observation does not *explain* behavior. It *describes* it. Nevertheless, descriptions can be revealing. We once thought, for example, that only humans use tools. Then naturalistic observation revealed that chimpanzees sometimes insert a stick in a termite mound and withdraw it, eating the stick's load of termites. Such unobtrusive naturalistic observations paved the way for later studies of animal thinking, language, and emotion, which further expanded our understanding of our fellow animals. Thanks to researchers' observations, we know that chimpanzees and baboons use deception: Psychologists repeatedly saw one young baboon pretending to have been attacked by another as a tactic to get its mother to drive the other baboon away from its food (Whiten & Byrne, 1988).

MICHAEL NICHOLS/National Geographic Creative

A natural observer

"Observations, made in the natural habitat, helped to show that the societies and behavior of animals are far more complex than previously supposed," chimpanzee observer Jane Goodall noted (1998).

Naturalistic observations also illuminate human behavior. Here are three findings you might enjoy:

- *A funny finding.* We humans laugh 30 times more often in social situations than in solitary situations (Provine, 2001). (Have you noticed how seldom you laugh when alone?)
- *Sounding out students.* What, really, are introductory psychology students

saying and doing during their everyday lives? To find out, Matthias Mehl and his colleagues (2010) equipped 79 such students with electronic recorders. Using this *experience sampling method*, the researchers then eavesdropped on more than 23,000 half-minute life slices of students' waking hours. Was happiness related to having simple talks or deeply involved conversations? The happiest participants avoided small talk and embraced meaningful conversations. Happy people would also rather talk than tweet. Does that surprise you?

- *Culture and the pace of life*. Naturalistic observation also enabled Robert Levine and Ara Norenzayan (1999) to compare the pace of life—walking speed, accuracy of public clocks, and so forth—in 31 countries. Their conclusion: Life is fastest paced in Japan and Western Europe, and slower paced in economically less-developed countries.

Naturalistic observation offers interesting snapshots of everyday life, but it does so without controlling for all the factors that may influence behavior. It's one thing to observe the pace of life in various places, but another to understand what makes some people walk faster than others. Nevertheless, descriptions can be revealing: The starting point of any science is description.

RETRIEVAL PRACTICE

Courtesy of Matthias Mehl

An EAR for naturalistic observation

Psychologists Matthias Mehl and James Pennebaker have used electronically activated recorders (EARs) to sample naturally occurring slices of daily life.

RP-5 What are the advantages and disadvantages of naturalistic observation, such as Mehl and his colleagues used in this study?

ANSWER: These researchers were able to carefully observe and record naturally occurring behaviors outside the artificiality of a laboratory. However, outside the lab they were not able to control for all the factors that may have influenced the everyday interactions they were recording.

See the **Video: Naturalistic Observation** for a helpful tutorial animation.

THE SURVEY A [survey](#) looks at many cases in less depth, asking people to

report their behavior or opinions. Questions about everything from sexual practices to political opinions are put to the public. In recent surveys:

- Compared with those born in the 1960s and 1970s, twice as many Millennials born in the 1990s reported having no sexual partners since age 18 (Twenge et al., 2016b).
- 1 in 5 people across 22 countries report believing that alien beings have come to Earth and now walk among us disguised as humans (Ipsos, 2010).
- 68 percent of all humans—some 5 billion people—say that religion is important in their daily lives (Diener et al., 2011).

survey a descriptive technique for obtaining the self-reported attitudes or behaviors of a particular group, usually by questioning a representative, *random sample* of the group.

But asking questions is tricky, and the answers often depend on how questions are worded and how respondents are chosen.

Wording Effects Even subtle changes in the order or wording of questions can have major effects. People are more approving of “aid to the needy” than of “welfare,” of “affirmative action” than of “preferential treatment,” of “not allowing” televised pornography than of “censoring” it, of “gun safety” laws than of “gun control” laws, and of “revenue enhancers” than of “taxes.” Because wording is such a delicate matter, critical thinkers will reflect on how the phrasing of a question might affect people’s expressed opinions.

Random Sampling In everyday thinking, we tend to generalize from samples we observe, especially vivid cases. An administrator who reads (a) a statistical summary of a professor’s student evaluations and (b) the vivid comments of two irate students may be influenced as much by the biased sample of two unhappy students as by the many favorable evaluations in the statistical summary. The temptation to succumb to the *sampling bias*—to generalize from a few vivid but unrepresentative cases—is nearly irresistible.

So how do you obtain a *representative sample*? Say you want to learn how students at your college or university feel about a proposed tuition increase. It’s often not possible to survey the whole group. How then could you choose

a group that would represent the total student body? Typically, you would seek a **random sample**, in which every person in the entire **population** has an equal chance of being in the sample group. You might number the names in the general student listing and then use a random number generator to pick your survey participants. (Sending each student a questionnaire wouldn't work because the conscientious people who returned it would not be a random sample.) Large representative samples are better than small ones, but a smaller representative sample of 100 is better than a larger unrepresentative sample of 500.

random sample a sample that fairly represents a population because each member has an equal chance of inclusion.

population all those in a group being studied, from which samples may be drawn. (Note: Except for national studies, this does not refer to a country's whole population.)

Political pollsters sample voters in national election surveys just this way. Using some 1500 randomly sampled people, drawn from all areas of a country, they can provide a remarkably accurate snapshot of the nation's opinions. Without random sampling, large samples—including unrepresentative call-in phone samples and TV or website polls—often give misleading results.

With very large samples, estimates become quite reliable. *E* is estimated to represent 12.7 percent of the letters in written English. *E*, in fact, is 12.3 percent of the 925,141 letters in Melville's *Moby-Dick*, 12.4 percent of the 586,747 letters in Dickens' *A Tale of Two Cities*, and 12.1 percent of the 3,901,021 letters in 12 of Mark Twain's works (*Chance News*, 1997).

The point to remember: Before accepting survey findings, think critically. Consider the sample. The best basis for generalizing is from a representative sample. You cannot compensate for an unrepresentative sample by simply adding more people.

RETRIEVAL PRACTICE

RP-6 What is an unrepresentative sample, and how do researchers avoid it?

ANSWER: An unrepresentative sample is a group that does not represent the entire population being studied. *Random sampling* helps researchers form a representative sample, because each member of the population has an equal chance of being included.

Correlation

LOQ 1-4 What does it mean when we say two things are correlated, and what are positive and negative correlations?

Describing behavior is a first step toward predicting it. Naturalistic observations and surveys often show us that one trait or behavior tends to coincide with another. In such cases, we say the two **correlate**. A statistical measure (the **correlation coefficient**) helps us figure how closely two things vary together, and thus how well either one *predicts* the other. Knowing how much aptitude test scores *correlate* with school success tells us how well the scores *predict* school success.

correlation a measure of the extent to which two factors vary together, and thus of how well either factor predicts the other.

correlation coefficient a statistical index of the relationship between two things (from -1.00 to $+1.00$).

Throughout this book, we will often ask how strongly two **variables** are related: For example, how closely related are the personality scores of identical twins? How well do intelligence test scores predict career achievement? How closely is stress related to disease? In such cases, **scatterplots** can be very revealing.

variable anything that can vary and is feasible and ethical to measure.

scatterplot a graphed cluster of dots, each of which represents the values of two variables. The slope of the points suggests the direction of the relationship between the two variables. The amount of scatter suggests the strength of the correlation (little scatter indicates high correlation).

Each dot in a scatterplot represents the values of two variables. The three scatterplots in [FIGURE 1.3](#) illustrate the range of possible correlations from a perfect positive to a perfect negative. (Perfect correlations rarely occur in the real world.) A correlation is positive if two sets of scores, such as for height and weight, tend to rise or fall together.

FIGURE 1.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1.3 Scatterplots, showing patterns of correlation

Correlations—abbreviated r —can range from +1.00 (scores for one variable increase in direct proportion to scores for another), to 0.00 (no relationship), to -1.00 (scores for one variable decrease precisely as scores rise for the other).

Saying that a correlation is “negative” says nothing about its strength. A correlation is negative if two sets of scores relate inversely, one set going up as the other goes down. The correlation between people’s height and the distance from their head to the ceiling is strongly (perfectly, in fact) negative.

Statistics can help us see what the naked eye sometimes misses. To demonstrate this for yourself, try an imaginary project. You wonder if tall men are more or less easygoing, so you collect two sets of scores: men’s heights and men’s temperaments. You measure the heights of 20 men, and you have someone else independently assess their temperaments from 0 (*extremely calm*) to 100 (*highly reactive*).

With all the relevant data right in front of you ([TABLE 1.1](#)), can you tell whether the correlation between height and reactive temperament is positive,

negative, or close to zero?

TABLE 1.1

Height and Temperamental Reactivity of 20 Men

Person	Height in Inches	<u>Temperament</u>
1	80	75
2	63	66
3	61	60
4	79	90
5	74	60
6	69	42
7	62	42
8	75	60
9	77	81
10	60	39
11	64	48
12	76	69
13	71	72
14	66	57
15	73	63
16	70	75
17	63	30
18	71	57
19	68	84
20	70	39

Comparing the columns in [Table 1.1](#), most people detect very little relationship between height and temperament. In fact, the correlation in this imaginary example is positive ($r = +0.63$), as we can see if we display the data as a scatterplot ([FIGURE 1.4](#)).

FIGURE 1.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1.4 Scatterplot for height and temperamental reactivity

This display of data from 20 imagined people (each represented by a data point) reveals an upward slope, indicating a positive correlation. The considerable scatter of the data indicates the correlation is much lower than $+1.00$.

If we fail to see a relationship when data are presented as systematically as in [Table 1.1](#), how much less likely are we to notice them in everyday life? To see what is right in front of us, we sometimes need statistical illumination. We can easily see evidence of gender discrimination when given statistically summarized information about job level, seniority, performance, gender, and salary. But we often see no discrimination when the same information dribbles in, case by case (Twiss et al., 1989).

The point to remember: A correlation coefficient helps us see the world more clearly by revealing the extent to which two things relate.

RETRIEVAL PRACTICE

RP-7 Indicate whether each association is a positive correlation or a negative correlation.

- . The more husbands viewed Internet pornography, the worse their marital

- relationships (Muusses et al., 2015). _____
- . The less sexual content teens saw on TV, the less likely they were to have sex (Collins et al., 2004). _____
 - . The longer children were breast-fed, the greater their later academic achievement (Horwood & Fergusson, 1998). _____
 - . The more income rose among a sample of poor families, the fewer psychiatric symptoms their children experienced (Costello et al., 2003). _____

ANSWER: 1. negative, 2. positive, 3. positive, 4. negative

For an animated tutorial on correlations, visit **Concept Practice: Positive and Negative Correlations**. See also the **Video: Correlational Studies** for another helpful tutorial animation.

ILLUSORY CORRELATION AND REGRESSION TOWARD THE MEAN

LOQ 1-5 What are illusory correlations, and what is regression toward the mean?

Correlations not only make visible the relationships we might otherwise miss, they also restrain our “seeing” nonexistent relationships. When we believe there is a relationship between two things, we are likely to notice and recall instances that confirm our belief. If we believe that dreams forecast actual events, we may notice and recall confirming instances more than disconfirming instances. The result is an [illusory correlation](#).

illusory correlation perceiving a relationship where none exists, or perceiving a stronger-than-actual relationship.

Illusory correlations can feed an illusion of control—that chance events are subject to our personal control. Gamblers, remembering their lucky rolls, may come to believe they can influence the roll of the dice by again throwing gently for low numbers and hard for high numbers. The illusion that

uncontrollable events correlate with our actions is also fed by a statistical phenomenon called [regression toward the mean](#). Average results are more typical than extreme results. Thus, after an unusual event, things tend to return toward their average level; extraordinary happenings tend to be followed by more ordinary ones.

regression toward the mean the tendency for extreme or unusual scores or events to fall back (regress) toward the average.

The point may seem obvious, yet we regularly miss it: We sometimes attribute what may be a normal regression (the expected return to normal) to something we have done. Consider two examples:

- Students who score much lower or higher on an exam than they usually do are likely, when retested, to return to their average.
- Unusual ESP subjects who defy chance when first tested nearly always lose their “psychic powers” when retested.

Failure to recognize regression is the source of many superstitions and of some ineffective practices as well. After berating an employee for poorer-than-usual performance a manager may—when the employee regresses to normal—feel rewarded for the “tough love.” After lavishing praise for an exceptionally fine performance, the manager may be disappointed when the employee’s behavior again migrates back toward his or her average. Ironically, then, regression toward the average can mislead us into feeling rewarded after criticizing others and feeling punished after praising them (Tversky & Kahneman, 1974).

“Once you become sensitized to it, you see regression everywhere.”

Psychologist Daniel Kahneman (1985)

The point to remember: When a fluctuating behavior returns to normal, there is no need to invent fancy explanations for why it does so. Regression toward the mean is probably at work.

RETRIEVAL PRACTICE

RP-8 You hear the school basketball coach telling her friend that she rescued her team's winning streak by yelling at the players after an unusually bad first half. What is another explanation of why the team's performance improved?

ANSWER: The team's poor performance was not their typical behavior. The return to their normal—their winning streak—may just have been a case of regression toward the mean.

So, although correlational research helpfully reveals relationships, it doesn't explain them. See [Thinking Critically About: Correlation and Causation](#).

Thinking Critically About:

Correlation and Causation

LOQ 1-6 Why do correlations enable prediction but not cause-effect explanation?

Mental illness *correlates* with smoking—meaning that those who experience mental illness are also more likely to be smokers.¹ Does this tell us anything about what *causes* mental illness or smoking? **NO.**

There may be something about smoking that leads to mental illness.

Those with mental illness may be more likely to smoke.

OR

There may be some *third variable*, such as a stressful home life, for example, that triggers *both* smoking and mental illness.

So, then, how would you interpret these recent findings:

- a) sexual hook-ups correlate with college women's experiencing depression, and
- b) *delaying* sexual intimacy correlates with positive outcomes such as greater relationship satisfaction and stability?²

Possible explanations:

1. Sexual restraint → Better mental health and stronger relationships
2. Depression → People being more likely to hook up
3. Some third factor, such as lower impulsivity → Sexual restraint, psychological well-being, and better relationships

Correlations do help us predict. Consider: Self-esteem correlates negatively with (and therefore predicts) depression. The lower people's self-esteem, the greater their risk for depression.

Possible interpretations:

1. Low self-esteem → Depression
2. Depression → Low self-esteem
3. Some third factor, such as distressing events or biological predisposition → Both low self-esteem and depression

You try it!
A survey of over 12,000 adolescents found that the more teens feel loved by their parents, the less likely they are to behave in unhealthy ways—having early sex, smoking, abusing alcohol and drugs, exhibiting violence.³ What are three possible ways we could interpret that finding?⁴

The point to remember: Correlation does not prove causation.
Correlation suggests a possible cause-effect relationship but does not prove it. Remember this principle and you will be wiser as you read and hear news of scientific studies.

1. Belluck, 2013. 2. Fielder et al., 2013; Willoughby et al., 2014. 3. Resnick et al., 1997. 4. ANSWERS: A. Parental love may produce healthy teens. B. Well-behaved teens may feel more parental love and approval. C. Some third factor, such as income or neighborhood, may influence both parental love AND teen behaviors.

Experimentation

LOQ 1-7 What are the characteristics of experimentation that make it possible to isolate cause and effect?

Happy are they, remarked the Roman poet Virgil, “who have been able to perceive the causes of things.” How might psychologists sleuth out the causes in correlational studies, such as the correlation between breast feeding and intelligence?

EXPERIMENTAL MANIPULATION Some researchers (not all) have found that breastfed infants develop higher childhood intelligence scores than do bottle-fed infants—an average 3 IQ point difference in a review of 17 studies (Horta et al., 2015; von Stumm & Plomin, 2015; Walfisch et al., 2014). Moreover, the longer infants breast feed, the higher their later IQ scores (Jedrychowski et al., 2012; Victora et al., 2015).

RETRIEVAL PRACTICE

© Nancy Brown/The Image Bank/Getty Images

Correlation need not mean causation.

RP-9 Length of marriage positively correlates with hair loss in men. Does this mean that marriage causes men to lose their hair (or that balding men make better husbands)?

ANSWER: In this case, as in many others, a third factor can explain the correlation: Golden anniversaries and baldness both accompany aging.

What do such findings mean? Do the nutrients of mother's milk contribute to brain development? Or do smarter mothers have smarter children? (Breast-fed children tend to be healthier and higher achieving than other children. But their bottle-fed siblings, born and raised in the same families, tend to be similarly healthy and high achieving [Colen & Ramey, 2014].) Even big data from a million or a billion mothers and their offspring couldn't tell us. To find answers to such questions—to isolate cause and effect—researchers must **experiment**. Experiments enable researchers to isolate the effects of one or more factors by (1) *manipulating the factors of interest* and (2) *holding constant* (“controlling”) *other factors*. To do so, they often create an **experimental group**, in which people receive the treatment, and a contrasting **control group** that does not receive the treatment. To minimize any preexisting differences between the two groups, researchers **randomly assign** people to the two conditions. Random assignment—whether with a random numbers table or flip of the coin—effectively equalizes the two groups. If one-third of the volunteers for an experiment can wiggle their ears, then about one-third of the people in each group will be ear wigglers. So, too, with age, attitudes, and other characteristics, which will be similar in the experimental and control groups. Thus, if the groups differ at the experiment's end, we can surmise that the treatment had an effect.

experiment a research method in which an investigator manipulates one or more factors (independent variables) to observe the effect on some behavior or mental process (the dependent variable). By *random assignment* of participants, the experimenter aims to control other relevant factors.

experimental group in an experiment, the group exposed to the treatment, that is, to one version of the independent variable.

control group in an experiment, the group *not* exposed to the treatment; contrasts with the experimental group and serves as a comparison for evaluating the effect of the treatment.

random assignment assigning participants to experimental and control groups by chance, thus minimizing preexisting differences between the different groups.

See the **Video: Random Assignment** for a tutorial animation.

Lane Oatey/blue jean images/Getty Images

Recall that in a well-done survey, *random sampling* is important. In an experiment, *random assignment* is equally important.

To experiment with breast feeding, one research team randomly assigned some 17,000 Belarus newborns and their mothers either to a control group given normal pediatric care or to an experimental group that promoted breast feeding, thus increasing expectant mothers' breast intentions (Kramer et al., 2008). At three months of age, 43 percent of the infants in the experimental group were being exclusively breast-fed, as were 6 percent in the control group. At age 6, when nearly 14,000 of the children were restudied, those who had been in the breast-feeding promotion group had intelligence test scores averaging six points higher than their control condition counterparts.

With parental permission, one British research team directly experimented with breast milk. They randomly assigned 424 hospitalized premature infants either to formula feedings or to breast-milk feedings (Lucas et al., 1992). Their finding: On intelligence tests taken at age 8, those nourished with breast milk scored significantly higher than those who were formula-fed. Breast was best.

No single experiment is conclusive, of course. But randomly assigning participants to one feeding group or the other effectively eliminated all factors except nutrition. If test performance changes when we vary infant

nutrition, then we infer that nutrition matters.

The point to remember: Unlike correlational studies, which uncover naturally occurring relationships, an experiment manipulates a factor to determine its effect.

PROCEDURES AND THE PLACEBO EFFECT Consider, then, how we might assess therapeutic interventions. Our tendency to seek new remedies when we are ill or emotionally down can produce misleading testimonies. If three days into a cold we start taking zinc tablets and find our cold symptoms lessening, we may credit the pills rather than the cold naturally subsiding. In the 1700s, bloodletting *seemed* effective. People sometimes improved after the treatment; when they didn't, the practitioner inferred the disease was too advanced to be reversed. So, whether or not a remedy is truly effective, enthusiastic users will probably endorse it. To determine its effect, we must control for other factors.

And that is precisely how new drugs and new methods of psychological therapy are evaluated ([Chapter 16](#)). Investigators randomly assign participants in these studies to research groups. One group receives a treatment (such as a medication). The other group receives a pseudotreatment—an inert *placebo* (perhaps a pill with no drug in it). The participants are often *blind* (uninformed) about what treatment, if any, they are receiving. If the study is using a [double-blind procedure](#), neither the participants nor those who administer the drug and collect the data will know which group is receiving the treatment.

double-blind procedure an experimental procedure in which both the research participants and the research staff are ignorant (blind) about whether the research participants have received the treatment or a placebo. Commonly used in drug-evaluation studies.

In double-blind studies, researchers check a treatment's actual effects apart from the participants' and the staff's belief in its healing powers. Just *thinking* you are getting a treatment can boost your spirits, relax your body, and relieve your symptoms. This [placebo effect](#) is well documented in reducing pain, depression, and anxiety (Kirsch, 2010). Athletes have run

faster when given a supposed performance-enhancing drug (McClung & Collins, 2007). Decaf-coffee drinkers have reported increased vigor and alertness—when they thought their brew had caffeine in it (Dawkins et al., 2011). People have felt better after receiving a phony mood-enhancing drug (Michael et al., 2012). And the more expensive the placebo, the more “real” it seems to us—a fake pill that costs \$2.50 worked better than one costing 10 cents (Waber et al., 2008). To know how effective a therapy really is, researchers must control for a possible placebo effect.

placebo [pluh-SEE-bo; Latin for “I shall please”]

effect experimental results caused by expectations alone; any effect on behavior caused by the administration of an inert substance or condition, which the recipient assumes is an active agent.

RETRIEVAL PRACTICE

RP-10 What measures do researchers use to prevent the *placebo effect* from confusing their results?

ANSWER: Research designed to prevent the placebo effect randomly assigns participants to an *experimental group* (which receives the real treatment) or to a *control group* (which receives a placebo). A double-blind procedure prevents people’s beliefs and hopes from affecting the results, because neither the participants nor those collecting the data know who receives the placebo. A comparison of the results will demonstrate whether the real treatment produces better results than *belief* in that treatment.

INDEPENDENT AND DEPENDENT VARIABLES Here is an even more potent example: The drug Viagra was approved for use after 21 clinical trials. One trial was an experiment in which researchers randomly assigned 329 men with erectile disorder to either an experimental group (Viagra takers) or a control group (placebo takers given an identical-looking pill). The

procedure was double-blind—neither the men taking the pills nor the person giving them knew what they were receiving. The result: At peak doses, 69 percent of Viagra-assisted attempts at intercourse were successful, compared with 22 percent for men receiving the placebo (Goldstein et al., 1998). Viagra performed.

This simple experiment manipulated just one factor: the drug (Viagra versus no Viagra). We call this experimental factor the **independent variable** because we can vary it *independently* of other factors, such as the men’s age, weight, and personality. Other factors that can potentially influence a study’s results are called **confounding variables**. Random assignment controls for possible confounding variables.

independent variable in an experiment, the factor that is manipulated; the variable whose effect is being studied.

confounding variable a factor other than the factor being studied that might influence a study’s results.

A similar experiment on a drug approved to increase women’s sexual arousal produced a result described as, um, anticlimactic—an additional “half of one satisfying sexual encounter a month” (Ness, 2016; Tavernise, 2016).

Experiments examine the effect of one or more independent variables on some measurable behavior, called the **dependent variable** because it can vary *depending* on what takes place during the experiment. Both variables are given precise *operational definitions*, which specify the procedures that manipulate the independent variable (the exact drug dosage and timing in this study) or measure the dependent variable (the men’s responses to questions about their sexual performance). These definitions answer the “What do you mean?” question with a level of precision that enables others to replicate the study. (See **FIGURE 1.5** for the British breast-milk experiment’s design.)

Random assignment
(controlling for other confounding variables
such as parental intelligence
and environment)

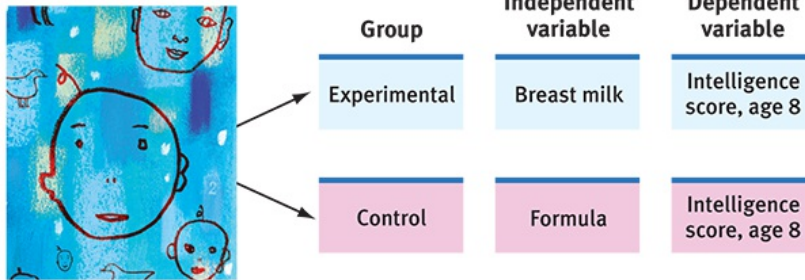

FIGURE 1.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
R. Michael Wertz

FIGURE 1.5 Experimentation

To discern causation, psychologists control for confounding variables by randomly assigning some participants to an experimental group, and others to a control group. Measuring the dependent variable (later intelligence test score) will determine the effect of the independent variable (type of milk).

dependent variable in an experiment, the outcome that is measured; the variable that may change when the independent variable is manipulated.

Let's pause to check your understanding using a simple psychology experiment: To test the effect of perceived ethnicity on the availability of rental housing, Adrian Carpusor and William Loges (2006) sent identically worded e-mail inquiries to 1115 Los Angeles-area landlords. The researchers varied the ethnic connotation of the sender's name and tracked the percentage of landlords' positive replies (invitations to view the apartment in person). "Patrick McDougall," "Said Al-Rahman," and "Tyrell Jackson" received, respectively, 89 percent, 66 percent, and 56 percent invitations. In this experiment, what was the independent variable? The dependent variable?³

"[We must guard] against not just racial slurs, but . . . against the subtle impulse to call Johnny back for a job interview, but not Jamal."

U.S. President Barack Obama, Eulogy for Clementa Pinckney, June 26, 2015

Experiments can also help us evaluate social programs. Do early childhood education programs boost impoverished children's chances for success? What are the effects of different antismoking campaigns? Do school sex-education programs reduce teen pregnancies? To answer such questions, we can experiment: If an intervention is welcomed but resources are scarce, we could use a lottery to randomly assign some people (or regions) to experience the new program and others to a control condition. If later the two groups differ, the intervention's effect will be supported (Passell, 1993).

Let's recap. A *variable* is anything that can vary (infant nutrition, intelligence, TV exposure—anything within the bounds of what is feasible and ethical to measure). Experiments aim to *manipulate* an *independent* variable, *measure* a *dependent* variable, and control *confounding* variables. An experiment has at least two different conditions: an *experimental condition* and a *comparison* or *control condition*. *Random assignment* works to minimize preexisting differences between the groups before any treatment effects occur. In this way, an experiment tests the effect of at least one independent variable (what we manipulate) on at least one dependent variable (the outcome we measure).

RETRIEVAL PRACTICE

RP-11 By using *random assignment*, researchers are able to control for _____, which are other factors besides the independent variable(s) that may influence research results.

ANSWER: confounding variables

RP-12 Match the term on the left with the description on the right.

- | | |
|---------------------------|---|
| 1. double-blind procedure | a. helps researchers generalize from a small set of survey responses to a larger population |
| 2. random sampling | b. helps minimize preexisting differences between experimental and control groups |
| 3. random assignment | c. controls for the placebo effect; neither researchers nor participants know who receives the real treatment |

ANSWER: 1. c, 2. a, 3. b

RP-13 Why, when testing a new drug to control blood pressure, would we learn more about its effectiveness from giving it to half of the participants in a group of 1000 than to all 1000 participants?

ANSWER: We learn more about the drug's effectiveness when we can compare the results of those who took the drug (the experimental group) with the results of those who did not (the control group). If we gave the drug to all 1000 participants, we would have no way of knowing whether the drug is serving as a placebo or is actually medically effective.

"If I don't think it's going to work, will it still work?"

Research Design

LOQ 1-8 How would you know which research design to use?

Throughout this book, you will read about amazing psychological science

discoveries. But how do we know fact from fiction? How do psychological scientists choose research methods and design their studies in ways that provide meaningful results? Understanding how research is done—how testable questions are developed and studied—is key to appreciating all of psychology. **TABLE 1.2** compares the features of psychology’s main research methods. In later chapters, you will read about other research designs, including *twin studies* ([Chapter 4](#)) and *cross-sectional* and *longitudinal research* ([Chapter 10](#)).

TABLE 1.2
Comparing Research Methods

Research Method	Basic Purpose	How Conducted	What Is Manipulated	Weaknesses
<i>Descriptive</i>	To observe and record behavior	Do case studies, naturalistic observations, or surveys	Nothing	No control of variables; single cases may be misleading
<i>Correlational</i>	To detect naturally occurring relationships; to assess how well one variable predicts another	Collect data on two or more variables; no manipulation	Nothing	Cannot specify cause and effect
<i>Experimental</i>	To explore cause and effect	Manipulate one or more factors; use random assignment	The independent variable(s)	Sometimes not feasible; results may not generalize to other contexts; not ethical to manipulate certain variables

In psychological research, no questions are off limits, except untestable ones: Does free will exist? Are people born evil? Is there an afterlife? Psychologists can’t test those questions. But they *can* test whether free will beliefs, aggressive personalities, and a belief in life after death influence how

people think, feel, and act (Dechesne et al., 2003; Shariff et al., 2014; Webster et al., 2014).

Having chosen their question, psychologists then select the most appropriate research design—*experimental, correlational, case study, naturalistic observation, twin study, longitudinal, or cross-sectional*—and determine how to set it up most effectively. They consider how much money and time are available, ethical issues, and other limitations. For example, it wouldn't be ethical for a researcher studying child development to use the experimental method and randomly assign children to loving versus punishing homes.

Next, psychological scientists decide how to measure the behavior or mental process being studied. For example, researchers could measure aggressive behavior by measuring participants' willingness to blast a stranger with intense noise.

To help you build your understanding, your critical thinking, and your *scientific literacy skills*, we created online Immersive Learning research activities. In these “How Would You Know?” activities, you get to play the role of the researcher, making choices about the best ways to test interesting questions. Some examples: How Would You Know If Having Children Relates to Being Happier?, How Would You Know If a Cup of Coffee Can Warm Up Relationships?, and How Would You Know If People Can Learn to Reduce Anxiety?

Researchers want to have confidence in their findings, so they carefully consider confounding variables—factors other than those being studied that may affect their interpretation of results.

Psychological research is a creative adventure. Researchers *design* each study, *measure* target behaviors, *interpret* results, and learn more about the fascinating world of behavior and mental processes along the way.

To review and test your understanding of research methods, visit **Concept Practice: Psychology's Research Methods and The Language of Experiments**, and the interactive **PsychSim 6: Understanding Psychological Research**. For a 9.5-minute synopsis of psychology's scientific research strategies, see the **Video: Research Methods**.

Predicting Everyday Behavior

LOQ 1-9 How can simplified laboratory conditions illuminate everyday life?

When you see or hear about psychological research, do you ever wonder whether people's behavior in the lab will predict their behavior in everyday life? Does detecting the blink of a faint red light in a dark room say anything useful about flying a plane at night? After viewing a violent, sexually explicit film, does a man's increased willingness to push buttons that deliver a noise blast to a woman really say anything about whether viewing violent pornography makes a man more likely to abuse a woman?

Before you answer, consider: The experimenter *intends* the laboratory environment to be a simplified reality—one that simulates and controls important features of everyday life. Just as a wind tunnel lets airplane designers re-create airflow forces under controlled conditions, a laboratory experiment lets psychologists re-create psychological forces under *controlled* conditions.

An experiment's purpose is not to re-create the exact behaviors of everyday life, but to test *theoretical principles* (Mook, 1983). In aggression studies, deciding whether to push a button that delivers a noise blast may not be the same as slapping someone in the face, but the principle is the same. *It is the resulting principles—not the specific findings—that help explain everyday behaviors.*

When psychologists apply laboratory research on aggression to actual violence, they are applying theoretical principles of aggressive behavior, principles they have refined through many experiments. Similarly, it is the principles of the visual system, developed from experiments in artificial settings (such as looking at red lights in the dark), that researchers apply to more complex behaviors such as night flying. And many investigations show that principles derived in the laboratory do typically generalize to the everyday world (Anderson et al., 1999).

The point to remember: Psychological science focuses less on specific behaviors than on revealing general principles that help explain many behaviors.

Psychology's Research Ethics

LOQ 1-10 Why do psychologists study animals, and what ethical guidelines safeguard human and animal research participants? How do psychologists' values influence psychology?

We have reflected on how a scientific approach can restrain biases. We have seen how case studies, naturalistic observations, and surveys help us describe behavior. We have also noted that correlational studies assess the association between two factors, showing how well one predicts another. We have examined the logic that underlies experiments, which use control conditions and random assignment of participants to isolate the effects of an independent variable on a dependent variable.

Yet, even knowing this much, you may still be approaching psychology with a mixture of curiosity and apprehension. So before we plunge in, let's entertain some common questions about psychology's ethics and values.

See the **Video: Research Ethics** for a helpful tutorial animation.

Protecting Research Participants

STUDYING AND PROTECTING ANIMALS Many psychologists study nonhuman animals because they find them fascinating. They want to understand how different species learn, think, and behave. Psychologists also study animals to learn about people. We humans are not *like* animals; we *are* animals, sharing a common biology. Animal experiments have therefore led to treatments for human diseases—insulin for diabetes, vaccines to prevent polio and rabies, transplants to replace defective organs.

Humans are complex. But the same processes by which we learn are present in rats, monkeys, and even sea slugs. The simplicity of the sea slug's nervous system is precisely what makes it so revealing of the neural mechanisms of learning.

“Rats are very similar to humans except that they are not stupid enough to purchase lottery tickets.”

Dave Barry, July 2, 2002

Sharing such similarities, should we not respect our animal relatives? The animal protection movement protests the use of animals in psychological, biological, and medical research. “We cannot defend our scientific work with animals on the basis of the similarities between them and ourselves and then defend it morally on the basis of differences,” noted Roger Ulrich (1991).

Out of this heated debate, two issues emerge. The basic one is whether it is right to place the well-being of humans above that of other animals. In experiments on stress and cancer, is it right that mice get tumors in the hope that people might not? Should some monkeys be exposed to an HIV-like virus in the search for an AIDS vaccine? Humans raise and slaughter 56 billion animals a year (Worldwatch Institute, 2013). Is our use and consumption of other animals as natural as the behavior of carnivorous hawks, cats, and whales?

“Please do not forget those of us who suffer from incurable diseases or disabilities who hope for a cure through research that requires the use of animals.”

Psychologist Dennis Feeney (1987)

For those who give human life top priority, a second question emerges: What safeguards should protect the well-being of animals in research? One survey of animal researchers gave an answer. Some 98 percent supported government regulations protecting primates, dogs, and cats, and 74 percent also supported regulations providing for the humane care of rats and mice (Plous & Herzog, 2000). Many professional associations and funding agencies already have such guidelines. British Psychological Society (BPS) guidelines call for housing animals under reasonably natural living conditions, with companions for social animals (Lea, 2000). American Psychological Association (APA) guidelines state that researchers must provide “humane care and healthful conditions” and that testing should “minimize discomfort” (APA, 2012). The European Parliament also mandates standards for animal care and housing (Vogel, 2010). Most universities screen research proposals, often through an animal care ethics

committee, and laboratories are regulated and inspected.

“The greatness of a nation can be judged by the way its animals are treated.”

Mahatma Gandhi, 1869–1948

Animals have themselves benefited from animal research. One Ohio team of research psychologists measured stress hormone levels in samples of millions of dogs brought each year to animal shelters. They devised handling and stroking methods to reduce stress and ease the dogs’ transition to adoptive homes (Tuber et al., 1999). Other studies have helped improve care and management in animals’ natural habitats. By revealing our behavioral kinship with animals and the remarkable intelligence of chimpanzees, gorillas, and other animals, experiments have also led to increased empathy and protection for them. At its best, a psychology concerned for humans and sensitive to animals serves the welfare of both.

STUDYING AND PROTECTING HUMANS What about human participants? Does the image of white-coated scientists seeming to deliver electric shocks trouble you? Actually, most psychological studies are free of such stress. Blinking lights, flashing words, and pleasant social interactions are more common. Moreover, psychology’s experiments are mild compared with the stress and humiliation often inflicted in reality TV “experiments.” In one episode of *The Bachelor*, a man dumped his new fiancée on camera, at the producers’ request, for the woman who earlier had finished second (Collins, 2009).

MARY ALTAFFER/AP Images

Animal research benefiting animals

Psychologists have helped zoos enrich animal environments, such as by reducing the “learned helplessness” of captivity by giving animals more choices (Kurtycz, 2015; Weir, 2013). Thanks partly to research on the benefits of novelty, control, and stimulation, these gorillas are enjoying an improved quality of life in New York’s Bronx Zoo.

Occasionally, though, researchers do temporarily stress or deceive people, but only when they believe it is essential to a justifiable end, such as understanding and controlling violent behavior or studying mood swings. Some experiments won’t work if participants know everything beforehand. (Wanting to be helpful, the participants might try to confirm the researcher’s predictions.)

The ethics codes of the APA and Britain’s BPS urge researchers to (1) obtain potential participants’ **informed consent** to take part, (2) protect participants from greater-than-usual harm and discomfort, (3) keep information about individual participants confidential, and (4) fully **debrief** people (explain the research afterward). As with nonhuman animals, most university ethics committees have guidelines that screen research proposals and safeguard human participants’ well-being.

informed consent giving potential participants enough information about a study to enable them to choose whether they wish to participate.

debriefing the postexperimental explanation of a study, including its purpose and any deceptions, to its participants.

Values in Psychology

Values affect what we study, how we study it, and how we interpret results. Researchers’ values influence choice of research topics. Should we study worker productivity or worker morale? Sex discrimination or gender differences? Conformity or independence? Values can also color “the facts”—our observations and interpretations; sometimes we see what we want or expect to see (**FIGURE 1.6**).

FIGURE 1.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Mike Kemp/Rubberball/Getty Images; The New Yorker Collection, Paul Noth, from cartoonbank.com.
All Rights Reserved.

FIGURE 1.6 What do you see? Our expectations influence what we perceive. Did you see a duck or a rabbit? Show some friends this image with the rabbit photo covered up and see if they are more likely to perceive a duck instead. (Inspired by Shepard, 1990.)

Even the words we use to describe traits and tendencies can reflect our values. In psychology and in everyday speech, labels describe and labels evaluate: One person's *rigidity* is another's *consistency*. One person's *undocumented worker* is another's *illegal alien*. One person's *faith* is another's *fanaticism*. One country's *enhanced interrogation techniques* become *torture* when practiced by an enemy. Our labeling someone as *firm* or *stubborn*, *careful* or *picky*, *discreet* or *secretive* reveals our own attitudes.

Popular applications of psychology also contain hidden values. If you defer to “professional” guidance about how to live—how to raise children, how to achieve self-fulfillment, how to respond to sexual feelings, how to get ahead at work—you are accepting value-laden advice. A science of behavior and mental processes can help us reach our goals. But it cannot decide what those goals should be.

If some people see psychology as merely common sense, others have a different concern—that it is becoming dangerously powerful. Might psychology be used to manipulate people?

Knowledge, like all power, can be used for good or evil. Nuclear power has been used to light up cities—and to demolish them. Persuasive power has been used to educate people—and to deceive them. Although psychology does have the power to deceive, its purpose is to enlighten. Every day,

psychologists explore ways to enhance learning, creativity, and compassion. Psychology speaks to many of our world's great problems—war, overpopulation, prejudice, family crises, crime—all of which involve attitudes and behaviors. Psychology also speaks to our deepest longings—for nourishment, for love, for happiness. Psychology cannot address all of life's great questions, but it speaks to some mighty important ones.

Psychology speaks

In making its historic 1954 school desegregation decision, the U.S. Supreme Court cited the expert testimony and research of psychologists Kenneth Clark and Mamie Phipps Clark (1947). The Clarks reported that, when given a choice between Black and White dolls, most African-American children chose the White doll, which seemingly indicated internalized anti-Black prejudice.

RETRIEVAL PRACTICE

RP-14 How are animal subjects and human research participants protected?

ANSWER: Animal protection legislation, laboratory regulation and inspection, and local and university ethics committees (which screen research proposals) attempt to safeguard

animal welfare. International psychological organizations urge researchers involving human participants to obtain *informed consent*, protect them from greater-than-usual harm and discomfort, treat their personal information confidentially, and *debrief* them fully at the end of the experiment.

REVIEW Research Strategies: How Psychologists Ask and Answer Questions

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

_____ refers to our tendency to perceive events as obvious or inevitable after the fact.

As scientists, psychologists

- a. keep their methods private so others will not repeat their research.
- b. assume the truth of articles published in leading scientific journals.
- c. reject evidence that competes with traditional findings.
- d. are willing to ask questions and to reject claims that cannot be verified by research.

Theory-based predictions are called _____.

Which of the following is NOT one of the *descriptive* methods psychologists use to observe and describe behavior?

- a. A case study
- b. Naturalistic observation
- c. Correlational research
- d. A phone survey

For your survey, you need to establish a group of people who represent the country's entire adult population. To do this, you will need to question a _____ sample of the population.

A study finds that the more childbirth training classes women attend, the less pain medication they require during childbirth. This finding can be stated as a _____ (positive/negative) correlation.

A _____ provides a visual representation of the direction and the strength of a relationship between two variables.

In a _____ correlation, the scores rise and fall together; in a _____ correlation, one score falls as the other rises.

- a. positive; negative
- b. positive; illusory
- c. negative; weak
- d. strong; weak

What is regression toward the mean, and how can it influence our interpretation of events?

Knowing that two events are correlated provides

- a. a basis for prediction.
- b. an explanation of why the events are related.
- c. proof that as one increases, the other also increases.
- d. an indication that an underlying third factor is at work.

Here are some recently reported correlations, with interpretations drawn by journalists. Knowing just these correlations, can you come up with other possible explanations for each of these?

- a. Alcohol use is associated with violence. (One interpretation: Drinking triggers or unleashes aggressive behavior.)
- b. Educated people live longer, on average, than less-educated people. (One interpretation: Education lengthens life and enhances health.)
- c. Teens engaged in team sports are less likely to use drugs, smoke, have sex, carry weapons, and eat junk food than are teens who do not engage in team sports. (One interpretation: Team sports encourage healthy living.)
- d. Adolescents who frequently see smoking in movies are more likely to smoke. (One interpretation: Movie stars' behavior influences impressionable teens.)

To explain behaviors and clarify cause and effect, psychologists use _____.

To test the effect of a new drug on depression, we randomly assign people to control and experimental groups. Those in the control group take a pill that contains no medication. This pill is a _____.

In a double-blind procedure,

- a. only the participants know whether they are in the control group or the experimental group.

- b. experimental and control group members will be carefully matched for age, sex, income, and education level.
- c. neither the participants nor the researchers know who is in the experimental group or control group.
- d. someone separate from the researcher will ask people to volunteer for the experimental group or the control group.

A researcher wants to determine whether noise level affects workers' blood pressure. In one group, she varies the level of noise in the environment and records participants' blood pressure. In this experiment, the level of noise is the _____.

The laboratory environment is designed to

- a. exactly re-create the events of everyday life.
- b. re-create psychological forces under *controlled* conditions.
- c. re-create psychological forces under *random* conditions.
- d. minimize the use of animals and humans in psychological research.

In defending their experimental research with animals, psychologists have noted that

- a. animals' physiology and behavior can tell us much about our own.
- b. animal experimentation sometimes helps animals as well as humans.
- c. animals are fascinating creatures and worthy of study.
- d. all of these statements are correct.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Statistical Reasoning in Everyday Life

In descriptive, correlational, and experimental research, statistics are tools that help us see and interpret what the unaided eye might miss. But accurate statistical understanding benefits everyone. To be an educated person today is to be able to apply simple statistical principles to everyday reasoning. One needn't memorize complicated formulas to think more clearly and critically about data.

Off-the-top-of-the-head estimates often misread reality and mislead the public. Someone throws out a big, round number. Others echo it, and before long the big, round number becomes public misinformation. Two examples:

- *Ten percent of people are gay or lesbian.* Or is it 2 to 4 percent, as suggested by various national surveys?
- *We ordinarily use only 10 percent of our brain.* Or is it closer to 100 percent?

When setting goals, we love big, round numbers. We're far more likely to want to lose 20 pounds than 19 or 21 pounds (or an even 10 kilograms rather than 9.07 kilograms). And by modifying their behavior, batters are nearly four times more likely to finish the season with a .300 average than with a .299 average (Pope & Simonsohn, 2011).

The point to remember: Doubt big, round, undocumented numbers. If you read that there are one million missing children, two million homeless, or three million spouse abusers, you can be pretty sure that someone is guessing. If they want to emphasize the problem, they will be motivated to guess big. If they want to minimize the problem, they will guess small.

Statistical illiteracy also feeds needless health scares (Gigerenzer, 2010). In the 1990s, the British press reported a study showing that women taking a

particular contraceptive pill had a 100 percent increased risk of blood clots that could produce strokes. This caused thousands of women to stop taking the pill, leading to a wave of unwanted pregnancies and an estimated 13,000 additional abortions (which also are associated with increased blood-clot risk). And what did the study actually find? A 100 percent increased risk, indeed—but only from 1 in 7000 to 2 in 7000. Such false alarms underscore the need to teach statistical reasoning and to present statistical information more transparently.

"Figures can be misleading—so I've written a song which I think expresses the real story of the firm's performance this quarter."

Patrick Hardin/Cartoonstock.com

Describing Data

LOQ 1-11 How do we describe data using three measures of central tendency, and what is the relative usefulness of the two measures of variation?

Once researchers have gathered their data, they may organize the data using *descriptive statistics*. One way to do this is to convert the data into a simple *bar graph*, as in [FIGURE 1.7](#), which displays a distribution of different brands of trucks still on the road after a decade. When reading statistical graphs such as this one, take care. It's easy to design a graph to make a difference look big ([Figure 1.7a](#)) or small ([Figure 1.7b](#)). The secret lies in how you label the

vertical scale (the *y*-axis).

FIGURE 1.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Transtock/SuperStock

FIGURE 1.7 Read the scale labels

RETRIEVAL PRACTICE

RP-15 An American truck manufacturer offered graph (a) below—with actual brand names included—to suggest the much greater durability of its trucks. What does graph (b) make clear about the varying durability, and how is this accomplished?

ANSWER: Note how the *y*-axis of each graph is labeled. The range for the *y*-axis label in graph (a) is only from 95 to 100. The range for graph (b) is from 0 to 100. All the trucks rank as 95% and up, so almost all are still functioning after 10 years, which graph (b) makes clear.

The point to remember: Think smart. When viewing graphs, read the scale labels and note their range.

Measures of Central Tendency

The next step is to summarize the data using some *measure of central tendency*, a single score that represents a whole set of scores. The simplest measure is the **mode**, the most frequently occurring score or scores. The most familiar is the **mean**, or arithmetic average—the total sum of all the scores

divided by the number of scores. The midpoint—the 50th percentile—is the **median**. On a divided highway, the median is the middle. So, too, with data: If you arrange all the scores in order from the highest to the lowest, half will be above the median and half will be below it.

mode the most frequently occurring score(s) in a distribution.

mean the arithmetic average of a distribution, obtained by adding the scores and then dividing by the number of scores.

median the middle score in a distribution; half the scores are above it and half are below it.

Measures of central tendency neatly summarize data. But consider what happens to the mean when a distribution is lopsided, when it's *skewed* by a few way-out scores. With income data, for example, the mode, median, and mean often tell very different stories (**FIGURE 1.8**). This happens because the mean is biased by a few extreme incomes. When Microsoft co-founder Bill Gates sits down in an intimate café, its average (mean) customer instantly becomes a billionaire. But the median customer's wealth remains unchanged. Understanding this, you can see why, according to the 2010 U.S. Census, nearly 65 percent of U.S. households have “below average” income. The bottom half of earners receive much less than half the national income cake. So, most Americans make less than average (the mean). Mean and median tell different true stories.

FIGURE 1.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1.8 A skewed distribution

This graphic representation of the distribution of a village's incomes illustrates the three measures of central tendency—mode, median, and mean. Note how just a few high incomes make the mean—the fulcrum

point that balances the incomes above and below—deceptively high.

The point to remember: Always note which measure of central tendency is reported. If it is a mean, consider whether a few atypical scores could be distorting it.

The average person has one ovary and one testicle.

Measures of Variation

Knowing the value of an appropriate measure of central tendency can tell us a great deal. But the single number omits other information. It helps to know something about the amount of *variation* in the data—how similar or diverse the scores are. Averages derived from scores with low variability are more reliable than averages based on scores with high variability. Consider a basketball player who scored between 13 and 17 points in each of the season's first 10 games. Knowing this, we would be more confident that she would score near 15 points in her next game than if her scores had varied from 5 to 25 points.

The **range** of scores—the gap between the lowest and highest—provides only a crude estimate of variation. A couple of extreme scores in an otherwise similar group, such as the \$950,000 and \$1,420,000 incomes in [Figure 1.8](#), will create a deceptively large range.

range the difference between the highest and lowest scores in a distribution.

The more useful standard for measuring how much scores deviate from one another is the **standard deviation**. It better gauges whether scores are packed together or dispersed, because it uses information from each score. The computation⁴ assembles information about how much individual scores differ from the mean, which can be very telling. Let's say test scores from Class A and Class B both have the same mean (75 percent correct), but very different standard deviations (5.0 for Class A and 15.0 for Class B). Have you ever had test experiences like that—where two-thirds of your classmates

in one course score in the 70 to 80 percent range, with scores in another course more spread out (two-thirds between 60 and 90)? The standard deviation, as well as the mean score, tell us about how each class is faring.

standard deviation a computed measure of how much scores vary around the mean score.

You can grasp the meaning of the standard deviation if you consider how scores naturally tend to be distributed in nature. Large numbers of data—heights, intelligence scores, life expectancy (though not incomes)—often form a symmetrical, *bell-shaped* distribution. Most cases fall near the mean, and fewer cases fall near either extreme. This bell-shaped distribution is so typical that we call the curve it forms the [normal curve](#).

normal curve (normal distribution) a symmetrical, bell-shaped curve that describes the distribution of many types of data; most scores fall near the mean (about 68 percent fall within one standard deviation of it) and fewer and fewer near the extremes.

As [FIGURE 1.9](#) shows, a useful property of the normal curve is that roughly 68 percent of the cases fall within one standard deviation on either side of the mean. About 95 percent of cases fall within two standard deviations. Thus, as [Chapter 10](#) notes, about 68 percent of people taking an intelligence test will score within ± 15 points of 100. About 95 percent will score within ± 30 points.

FIGURE 1.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 1.9 The normal curve

Scores on aptitude tests tend to form a normal, or bell-shaped, curve. For example, the most commonly used intelligence test, the Wechsler Adult Intelligence Scale, calls the average score 100.

RETRIEVAL PRACTICE

RP-16 The average of a distribution of scores is the _____. The score that shows up most often is the _____. The score right in the middle of a distribution (half the scores above it; half below) is the _____. We determine how much scores vary around the average in a way that includes information about the _____ of scores (difference between highest and lowest) by using the _____ formula.

ANSWER: mean; mode; median; range; standard deviation

For an interactive tutorial on these statistical concepts, visit **PsychSim 6: Descriptive Statistics**.

Significant Differences

LOQ 1-12 How do we know whether an observed difference can be

generalized to other populations?

Data are “noisy.” The average score in one group (children who were breast-fed as babies) could conceivably differ from the average score in another group (children who were bottle-fed) not because of any real difference but merely because of chance fluctuations in the people sampled. How confidently, then, can we infer that an observed difference is not just a fluke—a chance result from the research sample? For guidance, we can ask how reliable and statistically significant the differences are. These *inferential statistics* help us determine if results can be generalized to a larger population.

“The poor are getting poorer, but with the rich getting richer it all averages out in the long run.”

© The New Yorker Collection, 1988, Mirachi from cartoonbank.com. All Rights Reserved.

When Is an Observed Difference Reliable?

In deciding when it is safe to generalize from a sample, we should keep three principles in mind:

1. **Representative samples are better than biased samples.** The best basis for generalizing is not from the exceptional and memorable cases one finds at the extremes but from a representative sample of cases. Research never randomly samples the whole human population. Thus, it

pays to keep in mind what population a study has sampled.

2. ***Less-variable observations are more reliable than those that are more variable.*** As we noted earlier in the example of the basketball player whose game-to-game points were consistent, an average is more reliable when it comes from scores with low variability.
3. ***More cases are better than fewer.*** An eager prospective student visits two university campuses, each for a day. At the first, the student randomly attends two classes and discovers both instructors to be witty and engaging. At the next campus, the two sampled instructors seem dull and uninspiring. Returning home, the student (discounting the small sample size of only two teachers at each institution) tells friends about the “great teachers” at the first school and the “bores” at the second. Again, we know it but we ignore it: *Averages based on many cases are more reliable* (less variable) than averages based on only a few cases. After noticing that small schools were overrepresented among the most successful schools, several foundations invested in splitting larger schools into smaller ones—without realizing that small schools were also overrepresented among the *least* successful, because schools with fewer students have more variable outcomes (Nisbett, 2015). Again, more cases make for a more reliable average.

The point to remember: Smart thinkers are not overly impressed by a few anecdotes. Generalizations based on a few unrepresentative cases are unreliable.

When Is an Observed Difference Significant?

Perhaps you’ve compared men’s and women’s scores on a laboratory test of aggression, and found a gender difference. But individuals differ. How likely is it that the difference you observed was just a fluke? Statistical testing can estimate that.

Here is the underlying logic: When averages from two samples are each reliable measures of their respective populations (as when each is based on many observations that have small variability), then their *difference* is probably reliable as well. (Example: The less the variability in women’s and in men’s aggression scores, the more confidence we would have that any observed gender difference is reliable.) And when the difference between the

sample averages is *large*, we have even more confidence that the difference between them reflects a real difference in their populations.

In short, when sample averages are reliable, and when the difference between them is relatively large, we say the difference has **statistical significance**. This means that the observed difference is probably not due to chance variation between the samples.

statistical significance a statistical statement of how likely it is that an obtained result occurred by chance.

In judging statistical significance, psychologists are conservative. They are like juries who must presume innocence until guilt is proven. For most psychologists, proof beyond a reasonable doubt means not making much of a finding unless the odds of its occurring by chance, if no real effect exists, are less than 5 percent.

When reading about research, you should remember that, given large enough or homogeneous enough samples, a difference between them may be “statistically significant” yet have little *practical* significance. In one controversial study of nearly 700,000 Facebook users, researchers exposed people to status updates with more or with less positive words. Given the supersized sample’s “statistical power,” the tweaking produced a “statistically significant” but trivial effect. For example, those who received fewer posts with positive words responded with 0.1 percent fewer positive words themselves—a “statistically significant” effect, though one too tiny to be meaningful in the real world (Morin, 2014). Comparisons of intelligence test scores among hundreds of thousands of first-born and later-born individuals indicate a highly significant tendency for first-born individuals to have higher average scores than their later-born siblings (Rohrer et al., 2015; Zajonc & Markus, 1975). But because the scores differ by only one to three points, this “significant” difference has little practical importance.

Reprinted by permission of United Features Syndicate, Inc.

The point to remember: Statistical significance indicates the *likelihood* that a result could have happened by chance. But this does not say anything about the *importance* of the result.

RETRIEVAL PRACTICE

RP-17 Can you solve this puzzle?

The registrar's office at the University of Michigan has found that usually about 100 students in Arts and Sciences have perfect marks at the end of their first term at the University. However, only about 10 to 15 students graduate with perfect marks. What do you think is the most likely explanation for the fact that there are more perfect marks after one term than at graduation (Jepson et al., 1983)?

ANSWER: Averages based on fewer courses are more variable, which guarantees a greater number of extremely low and high marks at the end of the first term.

RP-18 _____ statistics summarize data, while _____ statistics determine if data can be generalized to other populations.

ANSWER: Descriptive; inferential

[statistical significance](#), p. 46

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Which of the three measures of central tendency is most easily distorted by a few very large or very small scores?

a. The mode

- b. The mean
- c. The median
- d. They are all equally vulnerable to distortion from atypical scores.

The standard deviation is the most useful measure of variation in a set of data because it tells us

- a. the difference between the highest and lowest scores in the set.
- b. the extent to which the sample being used deviates from the bigger population it represents.
- c. how much individual scores differ from the mode.
- d. how much individual scores differ from the mean.

Another name for a bell-shaped distribution, in which most scores fall near the middle and fewer scores fall at each extreme, is a

_____.

When sample averages are _____ and the difference between them is _____, we can say the difference has statistical significance.

- a. reliable; large
- b. reliable; small
- c. due to chance; large
- d. due to chance; small

THINKING CRITICALLY ABOUT: Using More Than 10 Percent of Our Brain

Responses to Damage

The Divided Brain

A Chinese transplant surgeon, Xiaoping Ren, is building an international team that hopes to undertake a really, really bold medical venture—a full-body transplant (Kean, 2016; Tatlow, 2016). Wang Huanming, who is paralyzed from the neck down, volunteered to become one of ten volunteers for this mind-boggling experiment. What would Wang have to do? Have his fully-functioning head transferred to a newly deceased, brain-dead person's still-functioning body.

Ignore for the moment the experiment's serious ethical issues, including the reality that the surgery will almost certainly end Wang's life (Kean, 2016). And ignore the seeming impossibility of precisely connecting the head-to-spinal-cord nerves. Imagine, just imagine, that the procedure could work! With the same brain and a new body, would Wang still be Wang? After recovering, to whose home should he return? If the old Wang was once a skilled musician, would the new Wang conceivably retain that skill—or would that depend on the muscle memories stored in the new body? And if he (assuming the new body was male) later had a child, whom should the birth certificate list as the father?

Most of us twenty-first-century people (you, too?) presume that, even with a new body, Wang would still be Wang. We presume that our brain, designed by our genes and sculpted by our experience, provides our identity and enables our mind. No brain, no mind.

We are, indeed, living brains, but more. We are bodies alive. No principle is more central to today's psychology, or to this book, than this: *Everything psychological is simultaneously biological*. Your every idea, every mood, every urge is a biological happening. You love, laugh, and cry with your body. To think, feel, or act without a body would be like running without legs. Without your body—your genes, your nervous system, your hormones, your appearance—you truly would be nobody. Moreover, your body and its brain influence and are influenced by your experience. Throughout this book,

you will find many examples of the interplay between biology and psychology.

As you will also see throughout this book, we humans share the same basic biological design. Yet thanks to our individual genes and experience, we differ from one another. Our traits and behaviors arise from the interaction of nature and nurture. Our thoughts, feelings, and actions influence our blood pressure, hormones, health—and our brain. As we travel from cradle to grave, our biology changes in response to our behaviors and environments.

In this chapter, we explore the mind's biology. We start small and build from the bottom up—from nerve cells up to the brain. But we'll also open the discussion of how our behavior and environment can influence our biology from the top down. Life changes us. You've heard it before and you'll hear it again: *Nurture works on what nature provides.*

Neural and Hormonal Systems

Biology, Behavior, and Mind

LOQ LEARNING OBJECTIVE QUESTION

2-1 Why are psychologists

concerned with human biology?

Our understanding of how the brain gives birth to the mind has come a long way. The ancient Greek physician, Hippocrates, correctly located the mind in the brain. His contemporary, the philosopher, Aristotle, believed the mind was in the heart, which pumps warmth and vitality to the body. The heart remains our symbol for love, but science has long since overtaken philosophy on this issue: It's your brain, not your heart, that falls in love.

In the early 1800s, German physician Franz Gall proposed that *phrenology*, studying bumps on the skull, could reveal a person's mental abilities and character traits ([FIGURE 2.1](#)). At one point, Britain had 29 phrenological societies, and phrenologists traveled North America giving skull readings (Dean, 2012; Hunt, 1993). Using a false name, humorist Mark Twain put one famous phrenologist to the test. "He found a cavity [and] startled me by saying that that cavity represented the total absence of the sense of humor!" Three months later, Twain sat for a second reading, this time identifying himself. Now "the cavity was gone, and in its place was . . . the loftiest bump of humor he had ever encountered in his life-long experience!" (Lopez, 2002). The "science" of phrenology remains known today as a reminder of our need for critical thinking and scientific analysis. Phrenology did at least succeed in focusing attention on the *localization of function*—the idea that various brain regions have particular functions.

FIGURE 2.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Bettmann/Getty Images

FIGURE 2.1 A wrongheaded theory

Despite initial acceptance of Franz Gall's speculations (far left), bumps on the skull tell us nothing about the brain's underlying functions. Nevertheless, some of his assumptions have held true. Though they are not the functions Gall proposed, different parts of the brain do control different aspects of behavior, as suggested here (near left; from *The Human Brain Book*), and as you will see throughout this chapter.

"You're certainly a lot less fun since the operation."

Gahan Wilson, from cartoonbank.com.
All Rights Reserved.

Today, we are living in a time Gall could only dream about. [Biological](#)

psychologists use advanced technologies to study the links between biological (genetic, neural, hormonal) processes and psychological processes. They and other researchers working from a biological perspective are announcing discoveries about the interplay of our biology and our behavior and mind at an exhilarating pace. Within little more than the past century, researchers seeking to understand the biology of the mind have discovered that

- our adaptive brain is wired by our experiences.
- among the body's cells are nerve cells that conduct electricity and "talk" to one another by sending chemical messages across a tiny gap that separates them.
- specific brain systems serve specific functions (though not the functions Gall supposed).
- we integrate information processed in these different brain systems to construct our experience of sights and sounds, meanings and memories, pain and passion.

biological psychology the scientific study of the links between biological (genetic, neural, hormonal) and psychological processes. Some biological psychologists call themselves *behavioral neuroscientists*, *neuropsychologists*, *behavior geneticists*, *physiological psychologists*, or *biopsychologists*.

We have also realized that we are each a system composed of subsystems that are in turn composed of even smaller subsystems. Tiny cells organize to form body organs. These organs form larger systems for digestion, circulation, and information processing. And those systems are part of an even larger system—the individual, who in turn is a part of a family, culture, and community. Thus, we are *biopsychosocial* systems. To understand our behavior, we need to study how these biological, psychological, and social systems work and interact. Let's begin with the brain's ability to rewire itself as it adapts to experience.

RETRIEVAL PRACTICE

RP-1 What do phrenology and biological psychology have in common?

ANSWER: They share a focus on the links between the brain and behavior. Phrenology faded because it had no scientific basis—skull bumps don't reveal mental traits and abilities.

The Power of Plasticity

LOQ 2-2 How do biology and experience interact?

Your brain is sculpted not only by your genes but also by your life. Under the surface of your awareness, your brain is constantly changing, building new pathways as it adjusts to little mishaps and new experiences. This neural change is called **plasticity**, and although this ability is strongest in childhood it continues throughout life (Gutchess, 2014). To see plasticity at work, consider London's taxi drivers.

plasticity the brain's ability to change, especially during childhood, by reorganizing after damage or by building new pathways based on experience.

How long do you think it would take to learn and remember 25,000 streets and their connections? London taxi driver trainees take two to four years to master this feat. For the half who pass the difficult final test, big rewards are in store: not only a better income but also an enlarged hippocampus, one of the brain's memory centers that processes spatial memories. London's bus drivers, who navigate a smaller set of roads, gain no similar neural rewards (Maguire et al., 2000, 2006).

Your brain is a work in progress. With repeated practice, it develops unique patterns that reflect your experiences. Consider the case of Daniel Kish, an enthusiastic adventurer and skilled cook who also happens to be completely blind. To “see” his surroundings, he has learned to use echolocation—clicking his tongue and listening to the sound's reverberation (Kish, 2015). We also see plasticity in well-practiced pianists, who have a

larger-than-usual auditory cortex area (a sound-processing region) that encodes piano sounds (Bavelier et al., 2000; Pantev et al., 1998). After years of practice, the brains of ballerinas and jugglers reflect other changes related to improved performance (Draganski et al., 2004; Hänggi et al., 2010; Herholz & Zatorre, 2012). Your brain, too, is changing as it reflects the practice and dedication you're devoting to the ideas, skills, and people you care about the most. The brain you were born with is not the brain you will die with.

Plasticity is part of what makes the human brain unique (Gómez-Robles et al., 2015). More than for any other species, our brain is designed to change. Our flexible brain enables changes large and small, through which we can adapt to our changing world.

Volker Corell Photography

The mind's eye

Daniel Kish, who is completely blind, enjoys going for walks in the woods. To stay safe, he uses echolocation—the same navigation method used by bats and dolphins. Blind echolocation experts such as Kish engage the brain's visual centers to navigate their surroundings (Thaler et al., 2011, 2014). Although Kish is blind, his flexible brain helps him to “see.”

Neural Communication

For scientists, it is a happy fact of nature that the information systems of humans and other animals operate similarly—so much so that you could not distinguish between small samples of brain tissue from a human and a monkey. This similarity allows researchers to study relatively simple animals, such as squids and sea slugs, to discover how our neural systems operate. It allows them to study other mammals' brains to understand the organization of our own. Cars differ, but all have engines, accelerators, steering wheels, and brakes. A space alien could study any one of them and grasp the operating principles. Likewise, animals differ, yet their nervous systems operate similarly.

Neurons

LOQ 2-3 What are neurons, and how do they transmit information?

Our body's neural information system is complexity built from simplicity. Its building blocks are **neurons**, or nerve cells. Throughout life, new neurons are born and unused neurons wither away (O'Leary et al., 2014; Shors, 2014). To fathom our thoughts and actions, our memories and moods, we must first understand how neurons work and communicate.

neuron a nerve cell; the basic building block of the nervous system.

Neurons differ, but all are variations on the same theme (**FIGURE 2.2**). Each consists of a **cell body** and its branching fibers. The often bushy **dendrite** fibers receive and integrate information, conducting it toward the cell body (Stuart & Spruston, 2015). From there, the cell's single lengthy **axon** fiber passes the message through its terminal branches to other neurons or to muscles or glands (**FIGURE 2.3**). *Dendrites listen. Axons speak.*

FIGURE 2.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.2 A motor neuron

cell body the part of a neuron that contains the nucleus; the cell's life-support center.

dendrites a neuron's often bushy, branching extensions that receive and integrate messages, conducting impulses toward the cell body.

axon the neuron extension that passes messages through its branches to other neurons or to muscles or glands.

FIGURE 2.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
David Scharf/Science Source

FIGURE 2.3 Neurons communicating

When we learn about neurons, we often see them one at a time to learn their parts. But our billions of neurons exist in a vast and densely interconnected web. One neuron's terminal branches send messages to neighboring dendrites. Read on to learn more about this complex and fascinating electrochemical communication process.

Unlike the short dendrites, axons may be very long, projecting several feet through the body. A human neuron carrying orders to a leg muscle, for example, has a cell body and axon roughly on the scale of a basketball attached to a 4-mile long rope. Much as home electrical wire is insulated, some axons are encased in a [myelin sheath](#), a layer of fatty tissue that insulates them and speeds their impulses. As myelin is laid down up to about age 25, neural efficiency, judgment, and self-control grow (Fields, 2008). If the myelin sheath degenerates, *multiple sclerosis* results: Communication to muscles slows, with eventual loss of muscle control.

myelin [MY-uh-lin] sheath a fatty tissue layer segmentally encasing the axons of some neurons; enables vastly greater transmission speed as neural impulses hop from one node to the next.

Supporting these billions of nerve cells are spidery [glial cells](#) (“glue cells”). Neurons are like queen bees; on their own they cannot feed or sheathe themselves. Glial cells are worker bees. They provide nutrients and insulating myelin, guide neural connections, and mop up ions and neurotransmitters. Glia also play a role in learning, thinking, and memory. By “chatting” with neurons, they participate in information transmission and memory (Fields, 2011, 2013; Martín et al., 2015).

glial cells (glia) cells in the nervous system that support, nourish, and protect neurons; they also play a role in learning, thinking, and memory.

In more complex animal brains, the proportion of glia to neurons increases. A postmortem analysis of Albert Einstein's brain did not find more

or larger-than-usual neurons, but it did reveal a much greater concentration of glial cells than found in an average person's head (Fields, 2004).

The Neural Impulse

Neurons transmit messages when stimulated by our senses or by neighboring neurons. A neuron sends a message by firing an impulse, called the **action potential**—a brief electrical charge that travels down its axon.

action potential a neural impulse; a brief electrical charge that travels down an axon.

Depending on the type of fiber, a neural impulse travels at speeds ranging from a sluggish 2 miles (3 kilometers) per hour to more than 200 miles (320 kilometers) per hour. But even its top speed is 3 million times slower than that of electricity through a wire. We measure brain activity in milliseconds (thousandths of a second) and computer activity in nanoseconds (billionths of a second). Thus, unlike the nearly instantaneous reactions of a computer, your reaction to a sudden event, such as a child darting in front of your car, may take a quarter-second or more. Your brain is vastly more complex than a computer, but slower at executing simple responses. And if you were an elephant—whose round-trip message travel time from a yank on the tail to the brain and back to the tail is 100 times longer than that of a tiny shrew—your reflexes would be slower yet (More et al., 2010).

“I sing the body electric.”

Walt Whitman, “Children of Adam,” 1855

Like batteries, neurons generate electricity from chemical events. In the neuron's chemistry-to-electricity process, *ions* (electrically charged atoms) are exchanged. The fluid outside an axon's membrane has mostly positively charged sodium ions. A resting axon's fluid interior (which includes both large, negatively charged protein ions and smaller, positively charged potassium ions) has a mostly negative charge. Like a tightly guarded facility,

the axon's surface is selective about what it allows through its gates. We say the axon's surface is *selectively permeable*. This positive-outside/negative-inside state is called the *resting potential*.

When a neuron fires, however, the security parameters change: The first section of the axon opens its gates, rather like a sewer cover flipping open, and positively charged sodium ions (attracted to the negative interior) flood in through the now-open channels (**FIGURE 2.4**). The loss of the inside/outside charge difference, called *depolarization*, causes the next section of axon channels to open, and then the next, like falling dominos. This temporary inflow of positive ions is the neural impulse—the action potential. Each neuron is itself a miniature decision-making device performing complex calculations as it receives signals from hundreds, even thousands, of other neurons. The mind boggles when imagining this electrochemical process repeating up to 100 or even 1000 times a second. But this is just the first of many astonishments.

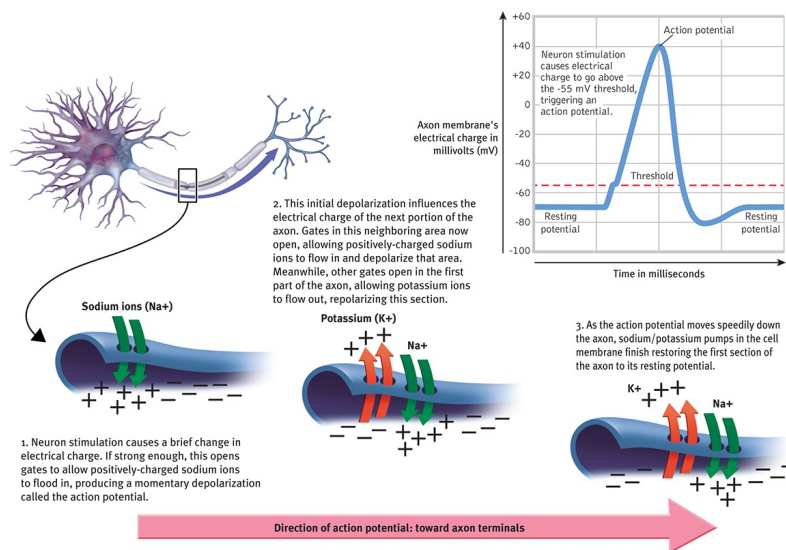

FIGURE 2.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.4 Action potential

Bodily sensations and actions—detecting a hug or kicking a soccer ball—happen when our neurons are stimulated enough that their membrane's electrical charge reaches a threshold (−55 mV in this example—see graph above right). This prompts each of those neurons to “fire” an impulse—an action potential—which travels down its axon (see numbered drawings above) and transmits a message to other neurons, muscles, or glands.

Most neural signals are *excitatory*, somewhat like pushing a neuron's gas pedal. Some are *inhibitory*, more like pushing its brake. If excitatory signals exceed the inhibitory signals by a minimum intensity, or **threshold** (see [Figure 2.4](#)), the combined signals trigger an action potential. (Think of it this way: If the excitatory party animals outvote the inhibitory party poopers, the party's on.) The action potential then travels down the axon, which branches into junctions with hundreds or thousands of other neurons or with the body's muscles and glands.

threshold the level of stimulation required to trigger a neural impulse.

Neurons need short breaks (a tiny fraction of an eyeblink). During a resting pause called the **refractory period**, subsequent action potentials cannot occur until the axon returns to its resting state. Then the neuron can fire again.

refractory period in neural processing, a brief resting pause that occurs after a neuron has fired; subsequent action potentials cannot occur until the axon returns to its resting state.

Increasing the level of stimulation above the threshold will not increase the neural impulse's intensity. The neuron's reaction is an **all-or-none response**: Like guns, neurons either fire or they don't. How, then, do we detect the intensity of a stimulus? How do we distinguish a gentle touch from a big hug? A strong stimulus can trigger *more* neurons to fire, and to fire more often. But it does not affect the action potential's strength or speed. Squeezing a trigger harder won't make a bullet go faster.

all-or-none response a neuron's reaction of either firing (with a full-strength response) or not firing.

RETRIEVAL PRACTICE

RP-2 When a neuron fires an action potential, the information travels through the axon, the dendrites, and the cell body, but not in that order. Place these three structures in the correct order.

ANSWER: dendrites, cell body, axon.

RP-3 How does our nervous system allow us to experience the difference between a slap and a tap on the back?

ANSWER: Stronger stimuli (the slap) cause more neurons to fire and to fire more frequently than happens with weaker stimuli (the tap).

“What one neuron tells another neuron is simply how much it is excited.”

Francis Crick, *The Astonishing Hypothesis*, 1994

For an animated explanation of this process, engage online with **Concept Practice: Action Potentials**.

“All information processing in the brain involves neurons ‘talking to’ each other at synapses.”

Neuroscientist Solomon H. Snyder (1984)

How Neurons Communicate

LOQ 2-4 How do nerve cells communicate with other nerve cells?

Neurons interweave so intricately that even with a microscope, you would have trouble seeing where one neuron ends and another begins. Scientists once believed that the axon of one cell fused with the dendrites of another in an uninterrupted fabric. Then British physiologist Sir Charles Sherrington

(1857–1952) noticed that neural impulses were taking an unexpectedly long time to travel a neural pathway. Inferring that there must be a brief interruption in the transmission, Sherrington called the meeting point between neurons a [synapse](#).

synapse [SIN-aps] the junction between the axon tip of the sending neuron and the dendrite or cell body of the receiving neuron. The tiny gap at this junction is called the *synaptic gap* or *synaptic cleft*.

We now know that the axon terminal of one neuron is in fact separated from the receiving neuron by a tiny *synaptic gap* (or *synaptic cleft*). Spanish anatomist Santiago Ramón y Cajal (1852–1934) marveled at these near-unions of neurons, calling them “protoplasmic kisses.” “Like elegant ladies air-kissing so as not to muss their makeup, dendrites and axons don’t quite touch,” noted poet Diane Ackerman (2004, [p. 37](#)). How do the neurons execute this protoplasmic kiss, sending information across the synaptic gap? The answer is one of the important scientific discoveries of our age.

When an action potential reaches the knob-like terminals at an axon’s end, it triggers the release of chemical messengers, called [neurotransmitters](#) ([FIGURE 2.5](#)). Within 1/10,000th of a second, the neurotransmitter molecules cross the synaptic gap and bind to receptor sites on the receiving neuron—as precisely as a key fits a lock. For an instant, the neurotransmitter unlocks tiny channels at the receiving site, and electrically charged atoms flow in, exciting or inhibiting the receiving neuron’s readiness to fire. The excess neurotransmitters finally drift away, are broken down by enzymes, or are reabsorbed by the sending neuron—a process called [reuptake](#). Some antidepressant medications work by partially blocking the reuptake of mood-enhancing neurotransmitters ([FIGURE 2.6](#)).

neurotransmitters chemical messengers that cross the synaptic gaps between neurons. When released by the sending neuron, neurotransmitters travel across the synapse and bind to receptor sites on the receiving neuron, thereby influencing whether that neuron will generate a neural impulse.

FIGURE 2.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.5 How neurons communicate

reuptake a neurotransmitter's reabsorption by the sending neuron.

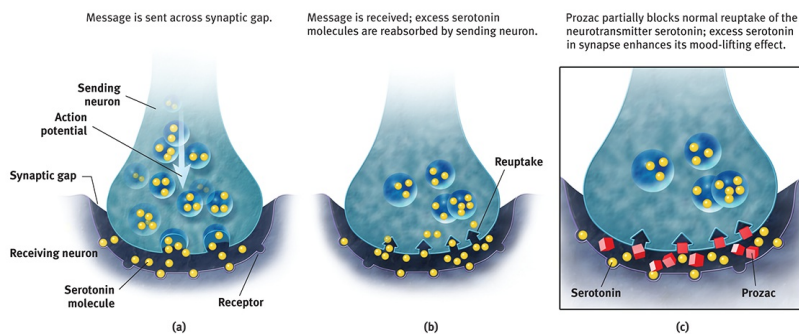

FIGURE 2.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.6 Biology of antidepressants

Selective serotonin reuptake inhibitors (SSRIs) are popularly prescribed antidepressants. They relieve depression by partially blocking the reuptake of the neurotransmitter serotonin. Shown here is the action of the SSRI Prozac.

RETRIEVAL PRACTICE

RP-4 What happens in the *synaptic gap*?

ANSWER: Neurons send neurotransmitters (chemical messengers)

across this tiny space between one neuron's terminal branch and the next neuron's dendrite or cell body.

RP-5 What is *reuptake*? What two other things can happen to excess neurotransmitters after a neuron reacts?

ANSWER: Reuptake occurs when excess neurotransmitters are reabsorbed by the sending neuron. Neurotransmitters can also drift away or be broken down by enzymes.

How Neurotransmitters Influence Us

LOQ 2-5 How do neurotransmitters influence behavior, and how do drugs and other chemicals affect neurotransmission?

In their quest to understand neural communication, researchers have discovered several dozen neurotransmitters and as many new questions: Are certain neurotransmitters found only in specific places? How do neurotransmitters affect our moods, memories, and mental abilities? Can we boost or diminish these effects through drugs or diet?

“When it comes to the brain, if you want to see the action, follow the neurotransmitters.”

Neuroscientist Floyd Bloom (1993)

Later chapters explore neurotransmitter influences on hunger and thinking, depression and euphoria, addictions and therapy. For now, let's glimpse how neurotransmitters influence our motions and emotions. A particular brain pathway may use only one or two neurotransmitters, such as serotonin and dopamine, and particular neurotransmitters affect specific behaviors and emotions ([TABLE 2.1](#)). But neurotransmitter systems don't operate in isolation; they interact, and their effects vary with the receptors they stimulate.

TABLE 2.1

Some Neurotransmitters and Their Functions

Neurotransmitter	Function	Examples of Malfunctions
<i>Acetylcholine (ACh)</i>	Enables muscle action, learning, and memory	With Alzheimer's disease, ACh-producing neurons deteriorate.
<i>Dopamine</i>	Influences movement, learning, attention, and emotion	Oversupply linked to schizophrenia. Undersupply linked to tremors and decreased mobility in Parkinson's disease.
<i>Serotonin</i>	Affects mood, hunger, sleep, and arousal	Undersupply linked to depression. Some drugs that raise serotonin levels are used to treat depression.
<i>Norepinephrine</i>	Helps control alertness and arousal	Undersupply can depress mood.
<i>GABA (gamma-aminobutyric acid)</i>	A major inhibitory neurotransmitter	Undersupply linked to seizures, tremors, and insomnia.
<i>Glutamate</i>	A major excitatory neurotransmitter; involved in memory	Oversupply can overstimulate the brain, producing migraines or seizures (which is why some people avoid MSG, monosodium glutamate, in food).
<i>Endorphins</i>	Neurotransmitters that influence the perception of pain or pleasure	Oversupply with opiate drugs can suppress the body's natural endorphin supply.

One of the best-understood neurotransmitters, *acetylcholine* (ACh), plays a role in learning and memory. It is also the messenger at every junction between motor neurons (which carry information from the brain and spinal cord to the body's tissues) and skeletal muscles. When ACh is released to our muscle cell receptors, the muscle contracts. If ACh transmission is blocked, as happens during some kinds of anesthesia and with some poisons, the muscles cannot contract and we are paralyzed.

Candace Pert and Solomon Snyder (1973) made an exciting discovery about neurotransmitters when they attached a radioactive tracer to morphine, an opiate drug that elevates mood and eases pain. (Radioactive tracers send out harmless but detectable energy as they pass through the body.) As the researchers tracked the morphine in an animal's brain, they noticed it was binding to receptors in areas linked with mood and pain sensations. But why would the brain have these "opiate receptors"? Why would it have a chemical lock, unless it also had a key—a natural painkiller—to open it?

Noam Galai/Getty Images;
ASSOCIATED PRESS

Dependent upon dopamine

The neurotransmitter dopamine helps us move, think, and feel. Too much increases the odds of developing schizophrenia; too little may produce the tremors and loss of motor control of Parkinson's disease (NIH, 2016). Approximately seven million people worldwide have Parkinson's disease (de Lau & Breteler, 2006). Well-known people

diagnosed with the disease include actor Michael J. Fox and the late boxing legend Muhammad Ali.

Researchers soon confirmed that the brain does indeed produce its own naturally occurring opiates. Our body releases several types of neurotransmitter molecules similar to morphine in response to pain and vigorous exercise. These **endorphins** (short for *endogenous* [produced within] *morphine*) help explain good feelings such as the “runner’s high,” the painkilling effects of acupuncture, and the indifference to pain in some severely injured people (Boecker et al., 2008; Fuss et al., 2015). But once again, new knowledge led to new questions.

endorphins [en-DOR-fins] “morphine within”—natural, opiate-like neurotransmitters linked to pain control and to pleasure.

RETRIEVAL PRACTICE

RP-6 Serotonin, dopamine, and endorphins are all chemical messengers called _____.

ANSWER: neurotransmitters

HOW DRUGS AND OTHER CHEMICALS ALTER

NEUROTRANSMISSION If natural endorphins lessen pain and boost mood, why not increase this effect by flooding the brain with artificial opiates, thereby intensifying the brain’s own “feel-good” chemistry? Because it would disrupt the brain’s chemical balancing act. When flooded with opiate drugs such as heroin and morphine, the brain, to maintain its chemical balance, may stop producing its own natural opiates. When the drug is withdrawn, the brain may then be deprived of any form of opiate, causing intense discomfort. For suppressing the body’s own neurotransmitter production, nature charges a price.

Physician Lewis Thomas, on the endorphins: “There it is, a biologically

universal act of mercy. I cannot explain it, except to say that I would have put it in had I been around at the very beginning, sitting as a member of a planning committee.”

The Youngest Science, 1983

Drugs and other chemicals affect brain chemistry, often by either exciting or inhibiting neurons’ firing. **Agonist** molecules *increase* a neurotransmitter’s action. Some agonists may increase the production or release of neurotransmitters, or block reuptake in the synapse. Other agonists may be similar enough to a neurotransmitter to bind to its receptor and mimic its excitatory or inhibitory effects. Some opiate drugs are agonists and produce a temporary “high” by amplifying normal sensations of arousal or pleasure.

agonist a molecule that increases a neurotransmitter’s action.

Antagonists *decrease* a neurotransmitter’s action by blocking production or release. Botulin, a poison that can form in improperly canned food, causes paralysis by blocking ACh release. (Small injections of botulin—Botox—smooth wrinkles by paralyzing the underlying facial muscles.) These antagonists are enough like the natural neurotransmitter to occupy its receptor site and block its effect, but are not similar enough to stimulate the receptor (rather like foreign coins that fit into, but won’t operate, a candy machine). Curare, a poison some South American Indians have applied to hunting-dart tips, occupies and blocks ACh receptor sites on muscles, producing paralysis in their prey.

antagonist a molecule that inhibits or blocks a neurotransmitter’s action.

RETRIEVAL PRACTICE

RP-7 Curare poisoning paralyzes its victims by blocking ACh receptors involved in muscle movements. Morphine mimics endorphin actions. Which is an agonist, and which is an

antagonist?

ANSWER: Morphine is an agonist; curare is an antagonist.

For an illustrated review of neural communication, visit **PsychSim 6: Neural Messages**.

The Nervous System

LOQ 2-6 What are the functions of the nervous system's main divisions, and what are the three main types of neurons?

Neurons communicating with neurotransmitters make up our body's **nervous system**, a communication network that takes in information from the world and the body's tissues, makes decisions, and sends back information and orders to the body's tissues (**FIGURE 2.7**).

nervous system the body's speedy, electrochemical communication network, consisting of all the nerve cells of the peripheral and central nervous systems.

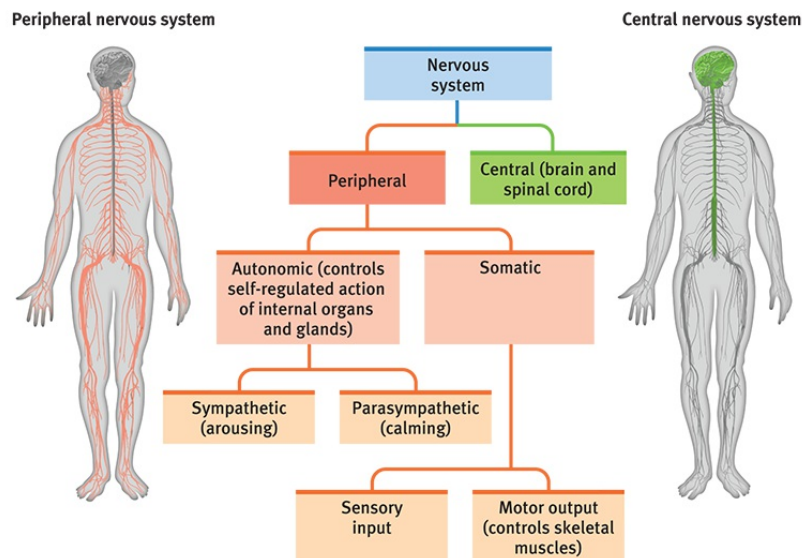

FIGURE 2.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.7 The functional divisions of the human nervous system

A quick overview: The brain and spinal cord form the [central nervous system \(CNS\)](#), the body's decision maker. The [peripheral nervous system \(PNS\)](#) is responsible for gathering information and for transmitting CNS decisions to other body parts. [Nerves](#), electrical cables formed from bundles of axons, link the CNS with the body's sensory receptors, muscles, and glands. The optic nerve, for example, bundles a million axons into a single cable carrying the messages from the eye to the brain (Mason & Kandel, 1991).

central nervous system (CNS) the brain and spinal cord.

peripheral nervous system (PNS) the sensory and motor neurons that connect the central nervous system (CNS) to the rest of the body.

nerves bundled axons that form neural cables connecting the central nervous system with muscles, glands, and sense organs.

Information travels in the nervous system through three types of neurons. [Sensory neurons](#) carry messages from the body's tissues and sensory receptors inward (thus, they are *afferent*) to the brain and spinal cord for processing. [Motor neurons](#) (which are *efferent*) carry instructions from the central nervous system outward to the body's muscles and glands. Between the sensory input and motor output, information is processed via [interneurons](#). Our complexity resides mostly in these interneurons. Our nervous system has a few million sensory neurons, a few million motor neurons, and billions and billions of interneurons.

sensory (afferent) neurons neurons that carry incoming information from the body's tissues and sensory receptors to the brain and spinal cord.

motor (efferent) neurons neurons that carry outgoing information from the brain and spinal cord to the muscles and glands.

interneurons neurons within the brain and spinal cord; they communicate internally and process information between the sensory inputs and motor outputs.

The Peripheral Nervous System

Our peripheral nervous system has two components—somatic and autonomic. Our [somatic nervous system](#) enables voluntary control of our skeletal muscles. As you reach the end of this page, your somatic nervous system will report to your brain the current state of your skeletal muscles and carry instructions back, triggering a response from your hand so you can read on.

somatic nervous system the division of the peripheral nervous system that controls the body's skeletal muscles. Also called the *skeletal nervous system*.

Our [autonomic nervous system \(ANS\)](#) controls our glands and our internal organ muscles. The ANS influences functions such as glandular activity, heartbeat, and digestion. (*Autonomic* means “self-regulating.”) Like an automatic pilot, this system may be consciously overridden, but usually operates on its own (autonomously).

autonomic [aw-tuh-NAHM-ik] nervous system (ANS) the part of the peripheral nervous system that controls the glands and the muscles of the internal organs (such as the heart). Its sympathetic division arouses; its parasympathetic division calms.

The autonomic nervous system's subdivisions serve two important functions ([FIGURE 2.8](#)). The [sympathetic nervous system](#) arouses and expends energy. If something alarms or challenges you (such as a longed-for job interview), your sympathetic nervous system will accelerate your heartbeat, raise your blood pressure, slow your digestion, raise your blood sugar, and cool you with perspiration, making you alert and ready for action. When the stress subsides (the interview is over), your [parasympathetic nervous system](#) will produce the opposite effects, conserving energy as it

calms you. The sympathetic and parasympathetic nervous systems work together to keep us in a steady internal state called *homeostasis*. (More on this in [Chapter 11](#).)

FIGURE 2.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.8 The dual functions of the autonomic nervous system

The autonomic nervous system controls the more autonomous (or self-regulating) internal functions. Its sympathetic division arouses and expends energy. Its parasympathetic division calms and conserves energy, allowing routine maintenance activity. For example, sympathetic stimulation accelerates heartbeat, whereas parasympathetic stimulation slows it.

sympathetic nervous system the division of the autonomic nervous system that arouses the body, mobilizing its energy.

parasympathetic nervous system the division of the autonomic nervous system that calms the body, conserving its energy.

I [DM] recently experienced my ANS in action. Before sending me into an MRI machine for a shoulder scan, the technician asked if I had issues with claustrophobia. “No, I’m fine,” I assured her, with perhaps a hint of macho swagger. Moments later, as I found myself on my back, stuck deep inside a coffin-sized box and unable to move, my sympathetic nervous system had a different idea. Claustrophobia overtook me. My heart began pounding, and I felt a desperate urge to escape. Just as I was about to cry out for release, I felt my calming parasympathetic nervous system kick in. My heart rate slowed and my body relaxed, though my arousal surged again before the 20-minute confinement ended. “You did well!” the technician said, unaware of my ANS roller-coaster ride.

RETRIEVAL PRACTICE

RP-8 Match the type of neuron to its description.

Type	Description
1. Motor neurons	a. carry incoming messages from sensory receptors to the CNS.
2. Sensory neurons	b. communicate within the CNS and process information between incoming and outgoing messages.
3. Interneurons	c. carry outgoing messages from the CNS to muscles and glands.

ANSWER: 1. c, 2. a, 3. b.

RP-9 What bodily changes does your ANS direct before and after you give an important speech?

ANSWER: Responding to this challenge, your ANS *sympathetic* division will arouse you. It accelerates your heartbeat, raises your blood pressure and blood sugar, slows your digestion,

and cools you with perspiration. After you give the speech, your *ANS parasympathetic* division will reverse these effects.

The Central Nervous System

From neurons “talking” to other neurons arises the complexity of the central nervous system’s brain and spinal cord.

It is the brain that enables our humanity—our thinking, feeling, and acting. Tens of billions of neurons, each communicating with thousands of other neurons, yield an ever-changing wiring diagram. By one estimate—projecting from neuron counts in small brain samples—our brain has some 86 billion neurons (Azevedo et al., 2009; Herculano-Houzel, 2012).

“The body is made up of millions and millions of crumbs.”

© Tom Swick/Cartoonstock.com

The brain’s neurons cluster into work groups called *neural networks*. To understand why, Stephen Kosslyn and Olivier Koenig (1992, [p. 12](#)) have invited us to “think about why cities exist; why don’t people distribute themselves more evenly across the countryside?” Like people networking with people, neurons network with nearby neurons with which they can have short, fast connections; each layer’s cells connect with various cells in the neural network’s next layer. Learning—to play the violin, speak a foreign language, or solve a math problem—occurs as experience strengthens

connections. Neurons that fire together wire together.

The other part of the CNS, the *spinal cord*, is a two-way information highway connecting the peripheral nervous system and the brain. Ascending neural fibers send up sensory information, and descending fibers send back motor-control information. The neural pathways governing our [reflexes](#), our automatic responses to stimuli, illustrate the spinal cord's work. A simple spinal reflex pathway is composed of a single sensory neuron and a single motor neuron. These often communicate through an interneuron. The knee-jerk response, for example, involves one such simple pathway. A headless warm body could do it.

reflex a simple, automatic response to a sensory stimulus, such as the knee-jerk response.

Another neural circuit enables the pain reflex ([FIGURE 2.9](#)). When your finger touches a flame, neural activity (excited by the heat) travels via sensory neurons to interneurons in your spinal cord. These interneurons respond by activating motor neurons leading to the muscles in your arm. Because the simple pain-reflex pathway runs through the spinal cord and right back out, your hand jerks away from the candle's flame *before* your brain receives and responds to the information that causes you to feel pain. That's why it feels as if your hand jerks away not by your choice, but on its own.

FIGURE 2.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.9 A simple reflex

Information travels to and from the brain by way of the spinal cord, unless that connection becomes broken (as in the case of full-body transplant volunteer Wang Huanming). Were the top of your spinal cord severed, you would not feel pain from your paralyzed body below. Nor would you feel pleasure. With your brain literally out of touch with your body, you would lose all sensation and voluntary movement in body regions with sensory and motor connections to the spinal cord below its point of injury. You would exhibit the knee-jerk response without feeling the tap. Men paralyzed below the waist may be capable of an erection (a simple reflex) if their genitals are stimulated (Goldstein, 2000). Women who are similarly paralyzed may respond with vaginal lubrication. But, depending on where and how completely their spinal cord is severed, they may be genitally unresponsive to erotic images and have no genital feeling (Kennedy & Over, 1990; Sipski et al., 1999). To produce bodily pain or pleasure, the sensory information must reach the brain.

“If the nervous system be cut off between the brain and other parts, the experiences of those other parts are nonexistent for the mind. The eye is blind, the ear deaf, the hand insensible and motionless.”

William James, *Principles of Psychology*, 1890

The Endocrine System

LOQ 2-7 How does the endocrine system transmit information and interact with the nervous system?

So far we have focused on the body's speedy electrochemical information system. Interconnected with your nervous system is a second communication system, the **endocrine system** (FIGURE 2.10). The endocrine system's glands secrete another form of chemical messengers, **hormones**, which travel through the bloodstream and affect other tissues, including the brain. When hormones act on the brain, they influence our interest in sex, food, and aggression.

endocrine [EN-duh-krin] **system** the body's "slow" chemical communication system; a set of glands that secrete hormones into the bloodstream.

FIGURE 2.10 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.10 The endocrine system

hormones chemical messengers that are manufactured by the endocrine glands, travel through the bloodstream, and affect other tissues.

Some hormones are chemically identical to neurotransmitters (the chemical messengers that diffuse across a synapse and excite or inhibit an adjacent neuron). The endocrine system and nervous system are therefore close relatives: Both produce molecules that act on receptors elsewhere. Like many relatives, they also differ. The speedier nervous system zips messages from eyes to brain to hand in a fraction of a second. Endocrine messages trudge along in the bloodstream, taking several seconds or more to travel from the gland to the target tissue. If the nervous system transmits information with text-message speed, the endocrine system delivers an old-fashioned letter.

But slow and steady sometimes wins the race. Endocrine messages tend to outlast the effects of neural messages. Have you ever felt angry long after the cause of your angry feelings was resolved (say, your friend apologized for her rudeness)? You may have experienced an “endocrine hangover” from lingering emotion-related hormones. The persistence of emotions—even without conscious awareness of what caused them—was dramatically evident in one ingenious experiment. Brain-damaged patients unable to form new conscious memories watched a sad film and later a happy film. After each viewing, they did not consciously recall the films, but the sad or happy emotion persisted (Feinstein et al., 2010).

In a moment of danger, the ANS orders the [adrenal glands](#) on top of the kidneys to release *epinephrine* and *norepinephrine* (also called *adrenaline* and *noradrenaline*). These hormones increase heart rate, blood pressure, and blood sugar, providing a surge of energy. When the emergency passes, the hormones—and the feelings—linger a while.

adrenal [ah-DREEN-el] glands a pair of endocrine glands that sit just above the kidneys and secrete hormones (epinephrine and norepinephrine) that help arouse the body in times of stress.

The most influential endocrine gland is the **pituitary gland**, a pea-sized structure located in the core of the brain, where it is controlled by an adjacent brain area, the *hypothalamus* (more on that shortly). Among the hormones released by the pituitary is a growth hormone that stimulates physical development. Another is *oxytocin*, which enables contractions associated with birthing, milk flow during nursing, and orgasm. Oxytocin also promotes pair bonding, group cohesion, and social trust (De Dreu et al., 2010; Zak, 2012). During a laboratory game, those given a nasal squirt of oxytocin rather than a placebo were more likely to trust strangers with their money and with confidential information (Kosfeld et al., 2005; Marsh et al., 2015; Mikolajczak et al., 2010). Some researchers remain skeptical that sniffing oxytocin reliably influences brain structures or trusting behavior (Nave et al., 2015). Others argue that oxytocin affects some people more than others (Bartz, 2016).

pituitary gland the endocrine system's most influential gland. Under the influence of the hypothalamus, the pituitary regulates growth and controls other endocrine glands.

Pituitary secretions also direct other endocrine glands to release their hormones. The pituitary, then, is a master gland (whose own master is the hypothalamus). For example, under the brain's influence, the pituitary triggers your sex glands to release sex hormones. These in turn influence your brain and behavior (Goetz et al., 2014). So, too, with stress. A stressful event triggers your hypothalamus to instruct your pituitary to release a hormone that causes your adrenal glands to flood your body with *cortisol*, a stress hormone that increases blood sugar.

This feedback system (brain → pituitary → other glands → hormones → body and brain) reveals the intimate connection of the nervous and endocrine systems. The nervous system directs endocrine secretions, which then affect the nervous system. Conducting and coordinating this whole electrochemical orchestra is that flexible maestro we call the brain.

RETRIEVAL PRACTICE

RP-10 Why is the pituitary gland called the “master gland”?

ANSWER: Responding to signals from the hypothalamus, the pituitary releases hormones that trigger other endocrine glands to secrete hormones, which in turn influence brain and behavior.

RP-11 How are the nervous and endocrine systems alike, and how do they differ?

ANSWER: Both of these communication systems produce chemical molecules that act on the body’s receptors to influence our behavior and emotions. The endocrine system, which secretes hormones into the bloodstream, delivers its messages much more slowly than the speedy nervous system, and the effects of the endocrine system’s messages tend to linger much longer than those of the nervous system.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

What do psychologists mean when they say the brain is “plastic”?

The neuron fiber that passes messages through its branches to other neurons or to muscles and glands is the _____.

The tiny space between the axon of one neuron and the dendrite or cell body of another is called the

- a. axon terminal.
- b. branching fiber.
- c. synaptic gap.
- d. threshold.

Regarding a neuron's response to stimulation, the intensity of the stimulus determines

- a. whether or not an impulse is generated.
- b. how fast an impulse is transmitted.
- c. how intense an impulse will be.
- d. whether reuptake will occur.

In a sending neuron, when an action potential reaches an axon terminal, the impulse triggers the release of chemical messengers

called _____.

Endorphins are released in the brain in response to

- a. morphine or heroin.
- b. pain or vigorous exercise.
- c. the all-or-none response.
- d. all of the above.

The autonomic nervous system controls internal functions, such as heart rate and glandular activity. The word autonomic means

- a. calming.
- b. voluntary.
- c. self-regulating.
- d. arousing.

The sympathetic nervous system arouses us for action and the parasympathetic nervous system calms us down. Together, the two systems make up the _____ nervous system.

The neurons of the spinal cord are part of the _____ nervous system.

The most influential endocrine gland, known as the “master gland,” is the

- a. pituitary.
- b. hypothalamus.
- c. thyroid.
- d. pancreas.

The _____ _____ secrete(s) epinephrine and norepinephrine, helping to arouse the body during times of stress.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Tools of Discovery, Older Brain Structures, and the Limbic System

We are convinced that we live “somewhere north of the neck” (Fodor, 1999). And for good reason: The brain enables the mind—seeing, hearing, smelling, feeling, remembering, thinking, speaking, dreaming. An acquaintance of mine [DM’s] received a new heart from a woman who, in a rare operation, had received a matched heart-lung transplant. When the two chanced to meet in their hospital ward, she introduced herself: “I think you have my heart.” But only her heart. Her self, she assumed, still resided inside her skull. It is the brain that self-reflectively analyzes the brain. When you think *about* your brain, you’re thinking *with* your brain—by releasing billions of neurotransmitter molecules across trillions of synapses. The effect of hormones on experiences such as love reminds us that we would not be of the same mind if we were a bodiless brain. Nevertheless, say neuroscientists, the *mind is what the brain does*. Brain, behavior, and cognition are an integrated whole. But precisely where and how are the mind’s functions tied to the brain? Let’s first see how scientists explore such questions.

“I am a brain, Watson. The rest of me is a mere appendix.”

Sherlock Holmes, in Arthur Conan Doyle’s “The Adventure of the Mazarin Stone,” 1921

The Tools of Discovery: Having Our Head Examined

LOQ **2-8** How do neuroscientists study the brain’s connections to behavior and mind?

For most of human history, scientists had no tools high powered yet gentle enough to reveal a living brain’s activity. Early case studies helped localize some brain functions. Damage to one side of the brain often caused numbness

or paralysis on the body's opposite side, suggesting that the body's right side is wired to the brain's left side, and vice versa. Damage to the back of the brain disrupted vision, and to the left-front part of the brain produced speech difficulties. Gradually, these early explorers were mapping the brain.

Robert Ludlow/UCL Institute of Neurology/Wellcome Images

A living human brain exposed

Today's neuroscience tools enable us to “look under the hood” and glimpse the brain at work, enabling the mind.

Now, within a lifetime, a new generation of neural mapmakers is charting

the known universe's most amazing organ. Scientists can also selectively **lesion** (destroy) tiny clusters of normal or defective brain cells, leaving the surrounding tissue unharmed. In the laboratory, such studies have revealed, for example, that damage to one area of the hypothalamus in a rat's brain reduces eating, to the point of starvation, whereas damage in another area produces overeating.

lesion [LEE-zhuhn] tissue destruction. A brain lesion is a naturally or experimentally caused destruction of brain tissue.

Today's neuroscientists can also *stimulate* various brain parts—electrically, chemically, or magnetically—and note the effect. Depending on the stimulated brain part, people may—to name a few examples—giggle, hear voices, turn their head, feel themselves falling, or have an out-of-body experience (Selimbeyoglu & Parvizi, 2010).

Scientists can even snoop on the messages of individual neurons. With tips small enough to detect the electrical pulse in a single neuron, modern microelectrodes can, for example, now detect exactly where the information goes in a cat's brain when someone strokes its whisker. Researchers can also eavesdrop on the chatter of billions of neurons and can see color representations of the brain's energy-consuming activity. Promising new tools include *optogenetics*, a technique that allows neuroscientists to control the activity of individual neurons (Boyden, 2014). By programming neurons to become receptive to light, researchers can examine the biological basis of fear, smell, memory, and various diseases (Drew et al., 2016; Gradinaru et al., 2009; Liu et al., 2012; Shusterman et al., 2011).

Right now, your mental activity is emitting telltale electrical, metabolic, and magnetic signals that would enable neuroscientists to observe your brain at work. Electrical activity in your brain's billions of neurons sweeps in regular waves across its surface. An **electroencephalogram (EEG)** is an amplified readout of such waves. Researchers record the brain waves through a shower-cap-like hat that is filled with electrodes covered with a conductive gel. Studying an EEG of the brain's activity is like studying a car engine by listening to its hum. With no direct access to the brain, researchers present a stimulus repeatedly and have a computer filter out brain activity unrelated to

the stimulus. What remains is the electrical wave evoked by the stimulus.

electroencephalogram (EEG) an amplified recording of the waves of electrical activity sweeping across the brain's surface. These waves are measured by electrodes placed on the scalp.

A related technique, **magnetoencephalography (MEG)**, measures magnetic fields from the brain's natural electrical activity. To isolate the brain's magnetic fields, researchers create special rooms that cancel out other magnetic signals, such as the Earth's magnetic field. Participants sit underneath a head coil that resembles a hair salon hairdryer. While participants complete activities, tens of thousands of neurons create electrical pulses, which in turn create magnetic fields. The speed and strength of the magnetic fields enable researchers to understand how certain tasks influence brain activity.

magnetoencephalography (MEG) a brain-imaging technique that measures magnetic fields from the brain's natural electrical activity.

"You must look into people, as well as at them," advised Lord Chesterfield in a 1746 letter to his son. Newer neuroimaging techniques give us that Superman-like ability to see inside the living brain. One such tool, the **PET (positron emission tomography) scan (FIGURE 2.11)**, depicts brain activity by showing each brain area's consumption of its chemical fuel, the sugar glucose. Active neurons gobble glucose. Our brain, though only about 2 percent of our body weight, consumes 20 percent of our calorie intake. After a person receives temporarily radioactive glucose, the PET scan can track the gamma rays released by this "food for thought" as a task is performed. Rather like weather radar showing rain activity, PET-scan "hot spots" show the most active brain areas as the person does mathematical calculations, looks at images of faces, or daydreams.

PET (positron emission tomography) scan a visual display of brain activity

that detects where a radioactive form of glucose goes while the brain performs a given task.

FIGURE 2.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Mark Harmel/The Image Bank/Getty Images

FIGURE 2.11 The PET scan

To obtain a PET scan, researchers inject volunteers with a low and harmless dose of a short-lived radioactive sugar. Detectors around the person's head pick up the release of gamma rays from the sugar, which has concentrated in active brain areas. A computer then processes and translates these signals into a map of the brain at work.

In [MRI \(magnetic resonance imaging\)](#) brain scans, the person's head is put in a strong magnetic field, which aligns the spinning atoms of brain molecules. Then, a radio-wave pulse momentarily disorients the atoms. When the atoms return to their normal spin, they emit signals that provide a detailed picture of soft tissues, including the brain. MRI scans have revealed a larger-than-average neural area in the left hemisphere of musicians who display perfect pitch (Schlaug et al., 1995). They have also revealed enlarged *ventricles*—fluid-filled brain areas (marked by the red arrows in [FIGURE 2.12](#))—in some patients who have schizophrenia, a disabling psychological disorder.

FIGURE 2.12 Myers/DeWall, *Psychology*, 12e,

From Daniel R. Weinberger, M.D., CBDB, NIMH

FIGURE 2.12 MRI scan of a healthy individual (left) and a person with schizophrenia (right)

Note the enlarged ventricle, the fluid-filled brain region at the tip of the arrow in the image on the right.

MRI (magnetic resonance imaging) a technique that uses magnetic fields and radio waves to produce computer-generated images of soft tissue. MRI scans show brain anatomy.

A special application of MRI—**fMRI (functional MRI)**—can reveal the brain’s functioning as well as its structure. Where the brain is especially active, blood goes. By comparing successive MRI scans, researchers can watch as specific brain areas activate, showing increased oxygen-laden bloodflow. As a person looks at a scene, for example, the fMRI machine detects blood rushing to the back of the brain, which processes visual information (see [TABLE 2.2](#) for a comparison of these techniques). When the brain is unoccupied, blood continues to flow via a web of brain regions called the *default network* (Mason et al., 2007). Default network brain activity supports mind-wandering and daydreaming (Christoff et al., 2009; Smallwood & Schooler, 2015).

fMRI (functional MRI) a technique for revealing bloodflow and, therefore, brain activity by comparing successive MRI scans. fMRI scans show brain function as well as structure.

TABLE 2.2

Types of Neural Measures

Name	How Does It Work?	Example
<i>Electroencephalogram (EEG)</i>	Electrodes placed on the scalp measure electrical activity in neurons.	Symptoms of depression and anxiety correlate with increased activity in the right frontal lobe, a brain area associated with behavioral withdrawal and negative emotion (Thibodeau et al., 2006).
<i>Magnetoencephalography (MEG)</i>	A head coil records magnetic fields from the brain's natural electrical currents.	Soldiers with posttraumatic stress disorder (PTSD), compared with those who do not have PTSD, show stronger magnetic fields in the visual cortex when they view trauma-related images (Todd et al., 2015).
<i>Positron emission tomography (PET)</i>	Tracks where a temporarily radioactive form of glucose goes while the brain of the person given it performs a given task.	Monkeys with an anxious temperament have brains that use more glucose in regions related to fear, memory, and expectations of reward and punishment (Fox et al., 2015).
<i>Magnetic resonance</i>	People sit or	People with a history of

<i>imaging (MRI)</i>	lie down in a chamber that uses magnetic fields and radio waves to provide a map of brain structure.	violence tend to have smaller frontal lobes, especially in regions that aid moral judgment and self-control (Glenn & Raine, 2014).
<i>Functional magnetic resonance imaging (fMRI)</i>	Measures bloodflow to brain regions by comparing continuous MRI scans.	Years after surviving a near plane crash, passengers who viewed material related to their trauma showed greater activation in the brain's fear, memory, and visual centers than when they watched footage related to the 9/11 terrorist attacks (Palombo et al., 2015).

Such snapshots of the brain's changing activity provide new insights into how the brain divides its labor. A mountain of recent fMRI studies suggests which brain areas are most active when people feel pain or rejection, listen to angry voices, think about scary things, feel happy, or become sexually excited. The technology enables a very crude sort of mind reading. One neuroscience team scanned 129 people's brains as they did eight different mental tasks (such as reading, gambling, or rhyming). Later, they were able, with 80 percent accuracy, to identify which of these mental activities their participants had been doing (Poldrack et al., 2009). Other research has used the brain's activity to predict future behavior, such as school performance, drug use, and the effectiveness of public health campaigns (Falk et al., 2012, 2016; Gabrieli et al., 2015).

Researchers now seek to go beyond examining how brain regions work independently. Analyses of *functional connectivity* help scientists understand

how well different brain regions work together, and can offer clues regarding the underlying causes of psychological disorders. For example, people with major depressive disorder tend to show low connectivity between brain regions involved in experiencing emotion and emotion regulation; these two types of brain regions don't "talk" very well (Kaiser et al., 2015). This poor neural communication may help explain why people with depression often struggle to regulate their emotions (Etkin et al., 2015; Miller et al., 2015).

You've seen the pictures—of colorful brains with accompanying headlines, such as "your brain on music." Hot brains make hot news (Bowers, 2016; Fine, 2010). In one study, students rated scientific explanations as more believable and interesting when they contained neuroscience (Fernandez-Duque et al., 2015). But "neuroskeptics" caution against overblown claims about any ability to predict customer preferences, detect lies, and foretell crime (Satel & Lilienfeld, 2013; Schwartz et al., 2016; Vul et al., 2009a, b). Neuromarketing, neurolaw, neuropolitics, and neurotheology are often neurohype. Imaging techniques illuminate brain structure and activity, and sometimes help us test different theories of behavior (Mather et al., 2013). But given that all human experience is brain-based, it's no surprise that different brain areas become active when one listens to a lecture or lusts for a lover.

To check your understanding of brain scans and their functions, engage online with **Concept Practice: Scanning the Brain**.

* * *

Today's techniques for peering into the thinking, feeling brain are doing for psychology what the microscope did for biology and the telescope did for astronomy. From them we have learned more about the brain in the last 30 years than in the previous 30,000. And the next decade will reveal much more, as each year massive funding goes into brain research. Europe's Human Brain Project promises \$1 billion for brain computer modeling. The PsychENCODE project enables researchers to examine differences between the brains of healthy people and those with various disorders, such as autism spectrum disorder, bipolar disorder, and schizophrenia (Akbarian et al., 2015). The \$40 million Human Connectome Project seeks "neural pathways [that] will reveal much about what makes us uniquely human and what makes

every person different from all others” (2013; Gorman, 2014; Smith et al., 2015). It harnesses the power of *diffusion spectrum imaging*, a type of MRI technology that maps long-distance brain fiber connections (Jarbo & Verstynen, 2015) ([FIGURE 2.13](#)). Such efforts have led to the creation of a new brain map with 100 neural centers not previously described (Glasser et al., 2016).

FIGURE 2.13 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Tom Barrick, Chris Clark, SGHMS/Science Source

FIGURE 2.13 Beautiful brain connections

The Human Connectome Project is using cutting-edge methods to map the brain’s interconnected network of neurons. Scientists create a multicolored “symphony” of neural fibers that transport water through different brain regions. These brain maps have helped identify over 100 new neural centers (Glasser et al., 2016).

To learn about the neurosciences now is like studying world geography when Magellan explored the seas. Today’s whole-brain mapping effort has been likened to last century’s Apollo program, which landed humans on the Moon. This truly is the golden age of brain science.

RETRIEVAL PRACTICE

RP-12 Match the scanning technique with the correct description.

Technique

Description

- a. tracks radioactive glucose to reveal brain

- | | |
|--------------|---|
| 1. fMRI scan | <i>activity.</i> |
| 2. PET scan | b. tracks successive images of brain tissue to show brain <i>function</i> . |
| 3. MRI scan | c. uses magnetic fields and radio waves to show brain <i>anatomy</i> . |

ANSWER: 1. b, 2. a, 3. c.

Older Brain Structures

LOQ 2-9 What structures make up the brainstem, and what are the functions of the brainstem, thalamus, reticular formation, and cerebellum?

Stefan Klein/
imagebroker/Alamy

An animal's capacities come from its brain structures. In primitive animals, such as sharks, a not-so-complex brain primarily regulates basic survival functions: breathing, resting, and feeding. In lower mammals, such as rodents, a more complex brain enables emotion and greater memory. In advanced mammals, such as humans, a brain that processes more information enables increased foresight as well.

The brain's increasing complexity arises from new systems built on top of the old, much as Earth's landscape covers the old with the new. Digging down, one discovers the fossil remnants of the past—brainstem components

performing for us much as they did for our distant ancestors. Let's start with the brain's base and work up to the newer systems.

For an introductory 12.5-minute overview of the brain, see the **Video: The Central Nervous System—Spotlight on the Brain.**

The Brainstem

The **brainstem** is the brain's oldest and innermost region. Its base is the **medulla**, the slight swelling in the spinal cord just after it enters the skull (**FIGURE 2.14**). Here lie the controls for your heartbeat and breathing. As some brain-damaged patients in a vegetative state illustrate, we need no higher brain or conscious mind to orchestrate our heart's pumping and lungs' breathing. The brainstem handles those tasks. Just above the medulla sits the **pons**, which helps coordinate movements and control sleep.

brainstem the oldest part and central core of the brain, beginning where the spinal cord swells as it enters the skull; the brainstem is responsible for automatic survival functions.

medulla [muh-DUL-uh] the base of the brainstem; controls heartbeat and breathing.

FIGURE 2.14 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.14 The brainstem and thalamus

The brainstem, including the pons and medulla, is an extension of the

spinal cord. The thalamus is attached to the top of the brainstem. The reticular formation passes through both structures.

If a cat's brainstem is severed from the rest of the brain above it, the animal will still breathe and live—and even run, climb, and groom (Klemm, 1990). But cut off from the brain's higher regions, it won't *purposefully* run or climb to get food.

The brainstem is a crossover point, where most nerves to and from each side of the brain connect with the body's opposite side ([FIGURE 2.15](#)). This peculiar cross-wiring is but one of the brain's many surprises.

FIGURE 2.15 Myers/DeWall,
Psychology, 12e,
© 2018 Worth Publishers
Andrew Swift

FIGURE 2.15 The body's wiring

The Thalamus

Sitting atop the brainstem is the [thalamus](#), a pair of egg-shaped structures that act as the brain's sensory control center ([Figure 2.14](#)). The thalamus receives information from all the senses except smell, and routes that information to the higher brain regions that deal with seeing, hearing, tasting, and touching. The thalamus also receives some of the higher brain's replies, which it then directs to the medulla and to the cerebellum (see below). For sensory information, your thalamus is something like London's Heathrow Airport, a hub through which traffic flows in and out on its way to various locations.

thalamus [THAL-uh-muss] the brain's sensory control center, located on top of the brainstem; it directs messages to the sensory receiving areas in the cortex and transmits replies to the cerebellum and medulla.

The Reticular Formation

Inside the brainstem, between your ears, lies the [reticular formation](#), a neuron network extending from the spinal cord right up through the thalamus. As the spinal cord's sensory input flows up to the thalamus, some of it travels through the reticular formation, which filters incoming stimuli and relays important information to other brain areas. Have you multitasked today? You can thank your reticular formation (Wimmer et al., 2015).

reticular formation a nerve network that travels through the brainstem into the thalamus and plays an important role in controlling arousal.

The reticular formation also controls arousal, as Giuseppe Moruzzi and Horace Magoun discovered in 1949. Electrically stimulating a sleeping cat's reticular formation almost instantly produced an awake, alert animal. When Magoun *severed* a cat's reticular formation without damaging nearby sensory pathways, the effect was equally dramatic: The cat lapsed into a coma from which it never awakened.

RETRIEVAL PRACTICE

RP-13 The _____ is a crossover point where nerves from the left side of the brain are mostly linked to the right side of the body, and vice versa.

ANSWER: brainstem

The Cerebellum

Extending from the rear of the brainstem is the baseball-sized [cerebellum](#), meaning “little brain,” which is what its two wrinkled halves resemble ([FIGURE 2.16](#)). The cerebellum (along with the *basal ganglia*, deep brain structures involved in motor movement) enables nonverbal learning and skill memory. It also helps us judge time, modulate our emotions, and discriminate sounds and textures (Bower & Parsons, 2003). And (with assistance from the pons) it coordinates voluntary movement. When a soccer player masterfully controls the ball, give the player’s cerebellum some credit. Under alcohol’s influence, coordination suffers. And if you injured your cerebellum, you would have difficulty walking, keeping your balance, or shaking hands. Your movements would be jerky and exaggerated. Gone would be any dreams of being a dancer or guitarist.

cerebellum [sehr-uh-BELL-um] the “little brain” at the rear of the brainstem; functions include processing sensory input, coordinating movement output and balance, and enabling nonverbal learning and memory.

FIGURE 2.16 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Sergio Torres/AP Images

FIGURE 2.16 The brain's organ of agility

Hanging at the back of the brain, the cerebellum coordinates our voluntary movements, as when soccer star Cristiano Ronaldo controls the ball.

* * *

Note: These older brain functions all occur without any conscious effort. This illustrates another of our recurring themes: *Our brain processes most information outside of our awareness.* We are aware of the *results* of our brain's labor—say, our current visual experience—but not *how* we construct the visual image. Likewise, whether we are asleep or awake, our brainstem manages its life-sustaining functions, freeing our newer brain regions to think, talk, dream, or savor a memory.

RETRIEVAL PRACTICE

RP-14 In what brain region would damage be most likely to (1) disrupt your ability to skip rope? (2) disrupt your ability to hear? (3) perhaps leave you in a coma? (4) cut off the very breath and heartbeat of life?

ANSWER: 1. cerebellum, 2. thalamus, 3. reticular formation, 4. medulla.

The Limbic System

LOQ 2-10 What are the limbic system's structures and functions?

We've considered the brain's oldest parts, but we've not yet reached its newest and highest regions, the *cerebral hemispheres* (the two halves of the brain). Between the oldest and newest brain areas lies the **limbic system** (*limbus* means "border"). This system contains the *amygdala*, the *hypothalamus*, and the *hippocampus* ([FIGURE 2.17](#)).

limbic system neural system (including the *amygdala*, *hypothalamus*, and *hippocampus*) located below the cerebral hemispheres; associated with emotions and drives.

FIGURE 2.17 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 2.17 The limbic system

This neural system sits between the brain's older parts and its cerebral hemispheres. The limbic system's hypothalamus controls the nearby pituitary gland.

The Amygdala

Research has linked the [amygdala](#), two lima-bean-sized neural clusters, to aggression and fear. In 1939, psychologist Heinrich Klüver and neurosurgeon Paul Bucy surgically removed a rhesus monkey's amygdala, turning the normally ill-tempered animal into the most mellow of creatures. In studies with other wild animals, including the lynx, wolverine, and wild rat, researchers noted the same effect. So, too, with human patients. Those with amygdala lesions often display reduced arousal to fear- and anger-arousing stimuli (Berntson et al., 2011). One such woman, patient S. M., has been called “the woman with no fear,” even if being threatened with a gun (Feinstein et al., 2013).

amygdala [uh-MIG-duh-la] two lima-bean-sized neural clusters in the limbic system; linked to emotion.

What then might happen if we electrically stimulated the amygdala of a normally placid domestic animal, such as a cat? Do so in one spot and the cat prepares to attack, hissing with its back arched, its pupils dilated, its hair on end. Move the electrode only slightly within the amygdala, cage the cat with a small mouse, and now it cowers in terror.

These and other experiments have confirmed the amygdala's role in fear and rage. One study found math anxiety associated with hyperactivity in the right amygdala (Young et al., 2012). Monkeys and humans with amygdala damage become less fearful of strangers (Harrison et al., 2015). Other studies link criminal behavior with amygdala dysfunction (Boccardi et al., 2011; Ermer et al., 2012). When people view angry and happy faces, only the angry ones increase activity in the amygdala (Mende-Siedlecki et al., 2013). But we must be careful. The brain is not neatly organized into structures that correspond to our behavior categories. When we feel afraid or act aggressively, there is neural activity in many areas of our brain—not just the amygdala. If you destroy a car's battery, it's true that you won't be able to start the engine. But the battery is merely one link in an integrated system.

RETRIEVAL PRACTICE

RP-15 Electrical stimulation of a cat's amygdala provokes angry reactions. Which *autonomic nervous system* division is activated by such stimulation?

ANSWER: The sympathetic nervous system

Jane Burton/Dorling Kindersley/Gettyimages

The Hypothalamus

Just below (*hypo*) the thalamus is the [hypothalamus](#) ([FIGURE 2.18](#)), an important link in the command chain governing bodily maintenance. Some neural clusters in the hypothalamus influence hunger; others regulate thirst, body temperature, and sexual behavior. Together, they help maintain a steady (*homeostatic*) internal state.

hypothalamus [hi-po-THAL-uh-muss] a neural structure lying below (*hypo*) the thalamus; it directs several maintenance activities (eating, drinking, body temperature), helps govern the endocrine system via the pituitary gland, and is linked to emotion and reward.

FIGURE 2.18 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
ISM/Phototake

FIGURE 2.18 The hypothalamus

This small but important structure, colored yellow/orange in this MRI scan, helps keep the body's internal environment in a steady state.

To monitor your body state, the hypothalamus tunes into your blood chemistry and any incoming orders from other brain parts. For example, picking up signals from your brain's cerebral cortex that you are thinking about sex, your hypothalamus will secrete hormones. These hormones will in turn trigger the adjacent “master gland” of the endocrine system, your pituitary (see [Figure 2.17](#)), to influence your sex glands to release *their* hormones. These hormones will intensify the thoughts of sex in your cerebral cortex. (Note the interplay between the nervous and endocrine systems: The brain influences the endocrine system, which in turn influences the brain.)

A remarkable discovery about the hypothalamus illustrates how progress in science often occurs—when curious, open-minded investigators make an unexpected observation. Two young McGill University neuropsychologists, James Olds and Peter Milner (1954), were trying to implant an electrode in a rat's reticular formation when they made a magnificent mistake: They placed the electrode incorrectly (Olds, 1975). Curiously, as if seeking more stimulation, the rat kept returning to the location where it had been stimulated by this misplaced electrode. On discovering that they had actually placed the device in a region of the hypothalamus, Olds and Milner realized they had stumbled upon a brain center that provides pleasurable rewards (Olds, 1975).

Later experiments located other “pleasure centers” (Olds, 1958). (What

the rats actually experience only they know, and they aren't telling. Rather than attribute human feelings to rats, today's scientists refer to *reward centers*, not "pleasure centers.") Just how rewarding are these reward centers? Enough to cause rats to self-stimulate these brain regions more than 1000 times per hour. Moreover, they would even cross an electrified floor that a starving rat would not cross to reach food.

In other species, including dolphins and monkeys, researchers later discovered other limbic system reward centers, such as the *nucleus accumbens* in front of the hypothalamus (Hamid et al., 2016). Animal research has also revealed both a general dopamine-related reward system and specific centers associated with the pleasures of eating, drinking, and sex. Animals, it seems, come equipped with built-in systems that reward activities essential to survival.

Researchers are experimenting with new ways of using brain stimulation to control nonhuman animals' actions in search-and-rescue operations. By rewarding rats for turning left or right, one research team trained previously caged rats to navigate natural environments (Talwar et al., 2002). By pressing buttons on a laptop, the researchers were then able to direct the rat—which carried a receiver, power source, and video camera all in a tiny backpack—to turn on cue, climb trees, scurry along branches, and return.

Do humans have limbic centers for pleasure? To calm violent patients, one neurosurgeon implanted electrodes in such areas. Stimulated patients reported mild pleasure; unlike Olds' rats, however, they were not driven to a frenzy (Deutsch, 1972; Hooper & Teresi, 1986). Moreover, newer research reveals that stimulating the brain's "hedonic hotspots" (its reward circuits) produces more *desire* than pure enjoyment (Kringelbach & Berridge, 2012). Experiments have also revealed the effects of a dopamine-related reward system in people. For example, dopamine release produces our pleasurable "chills" response to a favorite piece of music (Zatorre & Salimpoor, 2013).

Some researchers believe that substance use disorders may stem from malfunctions in natural brain systems for pleasure and well-being. People genetically predisposed to this *reward deficiency syndrome* may crave whatever provides that missing pleasure or relieves negative feelings (Blum et al., 1996).

“If you were designing a robot vehicle to walk into the future and survive, . . . you’d wire it up so that behavior that ensured the survival of the self or the species—like sex and eating—would be naturally reinforcing.”

Candace Pert (1986)

The Hippocampus

The [hippocampus](#)—a seahorse-shaped brain structure—processes conscious, explicit memories and decreases in size and function as we grow older. Humans who lose their hippocampus to surgery or injury also lose their ability to form new memories of facts and events (Clark & Maguire, 2016). Those who survive a hippocampal brain tumor in childhood struggle to remember new information in adulthood (Jayakar et al., 2015). National Football League players who experience a concussion may later have a shrunken hippocampus and poor memory (Strain et al., 2015). [Chapter 5](#) offers additional detail about how hippocampus size and function decrease as we grow older. [Chapter 8](#) explains how our two-track mind uses the hippocampus to process our memories.

hippocampus a neural center located in the limbic system; helps process explicit (conscious) memories—of facts and events—for storage.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only

help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The part of the brainstem that controls heartbeat and breathing is the

- a. cerebellum.
- b. medulla.
- c. cortex.
- d. thalamus.

The thalamus functions as a

- a. memory bank.
- b. balance center.
- c. breathing regulator.
- d. sensory control center.

The lower brain structure that governs arousal is the

- a. spinal cord.
- b. cerebellum.
- c. reticular formation.
- d. medulla.

The part of the brain that coordinates voluntary movement and enables nonverbal learning and memory is the _____.

Two parts of the limbic system are the amygdala and the

- a. cerebral hemispheres.
- b. hippocampus.
- c. thalamus.
- d. pituitary.

A cat's ferocious response to electrical brain stimulation would lead you to suppose the electrode had touched the _____.

The neural structure that most directly regulates eating, drinking, and body temperature is the

- a. endocrine system.
- b. hypothalamus.
- c. hippocampus.
- d. amygdala.

The initial reward center discovered by Olds and Milner was located in the _____.

The Cerebral Cortex

LOQ 2-11 What four lobes make up the cerebral cortex, and what are the functions of the motor cortex, somatosensory cortex, and association areas?

Older brain networks sustain basic life functions and enable memory, emotions, and basic drives. Newer neural networks within the *cerebrum*—the two cerebral hemispheres contributing 85 percent of the brain’s weight—form specialized work teams that enable our perceiving, thinking, and speaking. Like other structures above the brainstem (including the thalamus, hippocampus, and amygdala), the cerebral hemispheres come as a pair. Covering those hemispheres, like bark on a tree, is the [cerebral cortex](#), a thin surface layer of interconnected neural cells. In our brain’s evolutionary history, the cerebral cortex is a relative newcomer. It is your brain’s thinking crown, your body’s ultimate control and information-processing center.

cerebral [seh-REE-bruhl] **cortex** the intricate fabric of interconnected neural cells covering the cerebral hemispheres; the body’s ultimate control and information-processing center.

As we move up the ladder of animal life, the cerebral cortex expands, tight genetic controls relax, and the organism’s adaptability increases. Frogs and other small-cortex amphibians operate extensively on preprogrammed genetic instructions. The larger cortex of mammals offers increased capacities for learning and thinking, enabling them to be more adaptable. What makes us distinctively human mostly arises from the complex functions of our cerebral cortex.

The people who first dissected and labeled the brain used the language of scholars—Latin and Greek. Their words are actually attempts at graphic description: For example, *cortex* means “bark,” *cerebellum* is

“little brain,” and *thalamus* is “inner chamber.”

RETRIEVAL PRACTICE

RP-17 Which area of the human brain is most similar to that of less complex animals? Which part of the human brain distinguishes us most from less complex animals?

ANSWER: The brainstem; the cerebral cortex

Structure of the Cortex

If you opened a human skull, exposing the brain, you would see a wrinkled organ, shaped somewhat like the meat of an oversized walnut. Without these wrinkles, a flattened cerebral cortex would require triple the area—roughly that of a large pizza. The brain’s left and right hemispheres are filled mainly with axons connecting the cortex to the brain’s other regions. The cerebral cortex—that thin surface layer—contains some 20 to 23 billion of the brain’s nerve cells and 300 trillion synaptic connections (de Courten-Myers, 2005). Being human takes a lot of nerve.

Each hemisphere’s cortex is subdivided into four *lobes*, separated by prominent *fissures*, or folds ([FIGURE 2.20](#)). Starting at the front of your brain and moving over the top, there are the [frontal lobes](#) (behind your forehead), the [parietal lobes](#) (at the top and to the rear), and the [occipital lobes](#) (at the back of your head). Reversing direction and moving forward, just above your ears, you find the [temporal lobes](#). Each of the four lobes carries out many functions, and many functions require the interplay of several lobes.

FIGURE 2.20 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.20 The cortex and its basic subdivisions

frontal lobes the portion of the cerebral cortex lying just behind the forehead; involved in speaking and muscle movements and in making plans and judgments.

parietal [puh-RYE-uh-tuhl] lobes the portion of the cerebral cortex lying at the top of the head and toward the rear; receives sensory input for touch and body position.

occipital [ahk-SIP-uh-tuhl] lobes the portion of the cerebral cortex lying at the back of the head; includes areas that receive information from the visual fields.

temporal lobes the portion of the cerebral cortex lying roughly above the ears; includes the auditory areas, each receiving information primarily from the opposite ear.

Functions of the Cortex

More than a century ago, surgeons found damaged cortical areas during autopsies of people who had been partially paralyzed or speechless. This rather crude evidence did not prove that specific parts of the cortex control

complex functions like movement or speech. A laptop with a broken power cord might go dead, but we would be fooling ourselves if we thought we had “localized” the Internet in the cord.

Motor Functions

Scientists had better luck in localizing simpler brain functions. For example, in 1870, German physicians Gustav Fritsch and Eduard Hitzig made an important discovery: Mild electrical stimulation to parts of an animal’s cortex made parts of its body move. The effects were selective: Stimulation caused movement only when applied to an arch-shaped region at the back of the frontal lobe, running roughly ear-to-ear across the top of the brain. Moreover, stimulating parts of this region in the left or right hemisphere caused movements of specific body parts on the *opposite* side of the body. Fritsch and Hitzig had discovered what is now called the [motor cortex](#).

motor cortex an area at the rear of the frontal lobes that controls voluntary movements.

MAPPING THE MOTOR CORTEX Lucky for brain surgeons and their patients, the brain has no sensory receptors. Knowing this, in the 1930s, Otfrid Foerster and Wilder Penfield were able to map the motor cortex in hundreds of wide-awake patients by stimulating different cortical areas and observing responses. They discovered that body areas requiring precise control, such as the fingers and mouth, occupy the greatest amount of cortical space ([FIGURE 2.21](#)). In one of his many demonstrations of motor behavior mechanics, Spanish neuroscientist José Delgado stimulated a spot on a patient’s left motor cortex, triggering the right hand to make a fist. Asked to keep the fingers open during the next stimulation, the patient, whose fingers closed despite his best efforts, remarked, “I guess, Doctor, that your electricity is stronger than my will” (Delgado, 1969, [p. 114](#)).

FIGURE 2.21 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Right and left: BSIP/Science Source

FIGURE 2.21 Motor cortex and somatosensory cortex tissue devoted to each body part

As you can see from this classic though inexact representation, the amount of cortex devoted to a body part in the motor cortex (in the frontal lobes) or in the somatosensory cortex (in the parietal lobes) is not proportional to that body part's size. Rather, the brain devotes more tissue to sensitive areas and to areas requiring precise control. Thus, the fingers have a greater representation in the cortex than does the upper arm.

RETRIEVAL PRACTICE

RP-18 Try moving your right hand in a circular motion, as if cleaning a table. Then start your right foot doing the same motion, synchronized with your hand. Now reverse the right foot's motion, but not the hand's. Finally, try moving the *left* foot opposite to the right hand.

1. Why is reversing the right foot's motion so hard?
2. Why is it easier to move the left foot opposite to the right hand?

ANSWER: 1. The right limbs' opposed activities interfere with each other because both are controlled by the same (left) side of your brain. 2. Opposite sides of your brain control your left and right limbs, so the reversed motion causes less

interference.

More recently, scientists were able to predict a monkey's arm motion a tenth of a second *before* it moved—by repeatedly measuring motor cortex activity preceding specific arm movements (Gibbs, 1996). Such findings have opened the door to research on brain-controlled computer technology.

BRAIN-COMPUTER INTERFACES By eavesdropping on the brain, could we enable a paralyzed person to move a robotic limb? Could a brain-computer interface command a cursor to write an e-mail or do an online search? To find out, brain researchers implanted 100 tiny recording electrodes in the motor cortexes of three monkeys (Nicolelis, 2011; Serruya et al., 2002). As the monkeys gained rewards by using a joystick to follow a moving red target, the researchers matched the brain signals with the arm movements. Then they programmed a computer to monitor the signals and operate the joystick. When a monkey merely thought about a move, the mind-reading computer moved the cursor with nearly the same proficiency as had the reward-seeking monkey. In follow-up experiments, both monkeys and humans have learned to control a robot arm or wheelchair that could help them receive food (Collinger et al., 2013; Hochberg et al., 2012; Rajangam et al., 2016; Velliste et al., 2008; see [FIGURE 2.22](#)).

FIGURE 2.22 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
UPMC

FIGURE 2.22 Mind over matter

A neurodegenerative disease caused Jan's complete paralysis. Yet, thanks to a tiny, 96-electrode implant in her motor cortex, she and others have learned to direct a robotic arm with their thoughts (Collinger et al., 2013; Hochberg et al., 2012).

Research has also recorded messages not from the arm-controlling motor neurons, but from a brain area involved in planning and intention (Leuthardt et al., 2009; Musallam et al., 2004). In one study, a monkey seeking a juice reward awaited a cue telling it to reach toward a spot flashed on a screen in one of up to eight locations. A computer program captured the monkey's thinking by recording the associated activity. By matching this neural activity to the monkey's subsequent pointing, the mind-reading researchers could program a cursor to move in response to the monkey's thoughts. Monkey think, computer do.

If this technique works, why not use it to capture the words a person can think but cannot say (for example, after a stroke)? Cal Tech neuroscientist Richard Andersen (2005) and colleagues (2004) have speculated that researchers could implant electrodes in speech areas, then "ask a patient to think of different words and observe how the cells fire in different ways. So you build up your database, and then when the patient thinks of the word, you compare the signals with your database, and you can predict the words they're thinking. Then you take this output and connect it to a speech synthesizer. This would be identical to what we're doing for motor control." With this goal in mind, the U.S. Army has invested millions of dollars in neuroscientists' efforts to build a helmet that might read and transmit soldiers' thoughts (Piore, 2011).

Clinical trials of such *cognitive neural prosthetics* are now under way with people who have severe paralysis or have lost a limb (Andersen et al., 2010; Nurmikko et al., 2010). The first patient, a 25-year-old man with paralysis, was able to mentally control a TV, draw shapes on a computer screen, and play video games—all thanks to an aspirin-sized chip with 100 microelectrodes recording activity in his motor cortex (Hochberg et al., 2006). Since then, others with paralysis who have received implants have learned to direct robotic arms with their thoughts (Collinger et al., 2013; Hochberg et al., 2012). And then there is Ian Burkhart, who lost the use of his arms and legs several years ago at the age of 19. Ohio State University brain researchers implanted recording electrodes in his motor cortex (Bouton et al.,

2016). Using a technique called *machine learning*, they instruct Ian to stare at a computer screen that shows a moving hand. Next, Ian imagines moving his own hand. Brain signals from his motor cortex begin feeding into the computer, which gets the message that Ian wants to move his arm and thus stimulates those muscles. The result? Ian, with his very own paralyzed arm, grasps a bottle, dumps out its contents, and picks up a stick. “The things I do in the lab,” Ian says, “I would love to [do] in everyday life” (Marcus, 2016). If everything psychological is also biological—if, for example, every thought is also a neural event—microelectrodes could someday detect complex thoughts well enough to enable people to control their environment with ever-greater precision (see [FIGURE 2.23](#)).

FIGURE 2.23 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.23 Brain-computer interaction

Electrodes planted in a parietal lobe region involved with planning to reach out an arm could enable a person’s thoughts to move a robotic limb, stimulate muscles that activate a paralyzed limb, navigate a wheelchair, control a TV, and use the Internet (Andersen et al., 2010).

In another demonstration of machine learning, researchers scanned the brains of physics students when they thought about 30 physics-relevant concepts, such as gravity and momentum (Mason & Just, 2016). A computer program learned to accurately identify the links between specific brain region activations and the concepts.

Sensory Functions

If the motor cortex sends messages out to the body, where does the cortex

receive incoming messages? Wilder Penfield identified a cortical area—at the front of the parietal lobes, parallel to and just behind the motor cortex—that specializes in receiving information from the skin senses, such as touch and temperature, and from the movement of body parts. We now call this area the [somatosensory cortex](#). Stimulate a point on the top of this band of tissue and a person may report being touched on the shoulder; stimulate some point on the side and the person may feel something on the face.

somatosensory cortex an area at the front of the parietal lobes that registers and processes body touch and movement sensations.

The more sensitive the body region, the larger the somatosensory cortex area devoted to it ([Figure 2.21](#)). Your supersensitive lips project to a larger brain area than do your toes, which is one reason we kiss rather than touch toes. Rats have a large area of the brain devoted to their whisker sensations, and owls to their hearing sensations.

Scientists have identified additional areas where the cortex receives input from senses other than touch. Any visual information you are receiving now is going to the visual cortex in your occipital lobes, at the back of your brain ([FIGURES 2.24](#) and [2.25](#)). If you have normal vision, you might see flashes of light or dashes of color if stimulated in your occipital lobes. (In a sense, we *do* have eyes in the back of our head!) Having lost much of his right occipital lobe to a tumor removal, a friend of mine [DM's] was blind to the left half of his field of vision. Visual information travels from the occipital lobes to other areas that specialize in tasks such as identifying words, detecting emotions, and recognizing faces.

FIGURE 2.24 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Imperial College London

FIGURE 2.24 Seeing without eyes

The psychoactive drug LSD commonly produces vivid *hallucinations*. These fMRI (functional MRI) scans show dramatically increased connectivity of the visual cortex in the occipital lobes (color represents increased bloodflow) with other brain regions. In one scan (right), a research participant with closed eyes is under the influence of LSD. The other (left) shows the same person when given a placebo (Carhart-Harris et al., 2016; Cormier, 2016).

FIGURE 2.25 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 2.25 The visual cortex and auditory cortex

The visual cortex in the occipital lobes at the rear of your brain receives input from your eyes. The auditory cortex in your temporal lobes—

above your ears—receives information from your ears.

Any sound you now hear is processed by your auditory cortex in your temporal lobes (just above your ears; see [Figure 2.25](#)). Most of this auditory information travels a circuitous route from one ear to the auditory receiving area above your opposite ear. If stimulated in your auditory cortex, you might hear a sound. MRI scans of people with schizophrenia have revealed active auditory areas in the temporal lobes during the false sensory experience of auditory *hallucinations* (Lennox et al., 1999). Even the phantom ringing sound experienced by people with hearing loss is—if heard in one ear—associated with activity in the temporal lobe on the brain’s opposite side (Muhlnickel, 1998).

RETRIEVAL PRACTICE

RP-19 Our brain’s _____ cortex registers and processes body touch and movement sensations. The _____ cortex controls our voluntary movements.

ANSWER: somatosensory; motor

Association Areas

So far, we have pointed out small cortical areas that either receive sensory input or direct muscular output. Together, these occupy about one-fourth of the human brain’s thin, wrinkled cover. What, then, goes on in the remaining vast regions of the cortex? In these [association areas](#), neurons are busy with higher mental functions—many of the tasks that make us human. Electrically probing an association area won’t trigger any observable response. So, unlike the somatosensory and motor areas, association area functions cannot be neatly mapped. Does this mean we don’t use them? See *Thinking Critically About: Using More Than 10 Percent of Our Brain*.

association areas areas of the cerebral cortex that are not involved in primary motor or sensory functions; rather, they are involved in higher mental functions such as learning, remembering, thinking, and speaking.

Association areas are found in all four lobes. The *prefrontal cortex* in the forward part of the frontal lobes enables judgment, planning, and processing of new memories (de la Vega et al., 2016). People with damaged frontal lobes may have high intelligence test scores and great cake-baking skills. Yet they would not be able to plan ahead to *begin* baking a cake for a birthday party (Huey et al., 2006). And if they did begin to bake, they might forget the recipe (MacPherson et al., 2016).

Frontal lobe damage also can alter personality and remove a person's inhibitions. Consider the classic case of railroad worker Phineas Gage. One afternoon in 1848, Gage, then 25 years old, was using a tamping iron to pack gunpowder into a rock. A spark ignited the gunpowder, shooting the rod up through his left cheek and out the top of his skull, leaving his frontal lobes damaged (**FIGURE 2.26**). To everyone's amazement, Gage was immediately able to sit up and speak, and after the wound healed, he returned to work. But having lost some of the neural tracts that enabled his frontal lobes to control his emotions, the affable, soft-spoken man was now irritable, profane, and dishonest (Van Horn et al., 2012). This person, said his friends, was "no longer Gage." His mental abilities and memories were unharmed, but his personality was not. (Gage later lost his railroad job, but over time, he

adapted to his injury and found work as a stagecoach driver [Macmillan & Lena, 2010].)

Gift of Jack and Beverly Wilgus

FIGURE 2.26 A blast from the past

(a) Phineas Gage's skull was kept as a medical record. Using measurements and modern neuroimaging techniques, researchers have reconstructed the probable path of the rod through Gage's brain (Van Horn et al., 2012). (b) This photo shows Gage after his accident. (The image has been reversed to show the features correctly. Early photos, including this one, were actually mirror images.)

See the **Video: Case Studies** for a helpful tutorial animation.

Studies of others with damaged frontal lobes have revealed similar impairments. Not only may they become less inhibited (without the frontal lobe brakes on their impulses), but their moral judgments may seem unrestrained. Cecil Clayton lost 20 percent of his left frontal lobe in a 1972 sawmill accident. Thereafter, his intelligence test score dropped to an elementary school level and he displayed increased impulsivity. In 1996, he fatally shot a deputy sheriff. In 2015, when he was 74, the State of Missouri executed him (Williams, 2015).

Cecil Clayton's brain scan, included with request for stay of execution filed with the Supreme Court, showing a missing portion of his frontal lobe.

Missing frontal lobe brakes

With part of his left frontal lobe (in this downward-facing brain scan) lost to injury, Cecil Clayton became more impulsive and killed a deputy sheriff. Nineteen years later, his state executed him for this crime.

Would you advocate pushing one person in front of a runaway trolley to save five others? Most people would not, but those with damage to the prefrontal cortex are often untroubled by such ethical dilemmas (Koenigs et al., 2007). The frontal lobes help steer us away from violent actions (Molenberghs et al., 2015; Yang & Raine, 2009). With their frontal lobes ruptured, people's moral compass seems to disconnect from their behavior.

Association areas also perform other mental functions. The parietal lobes, parts of which were large and unusually shaped in Einstein's normal-weight brain, enable mathematical and spatial reasoning (Burrell, 2015; Ibos & Freedman, 2014). Stimulation of one parietal lobe area in brain-surgery patients produced a feeling of wanting to move an upper limb, the lips, or the tongue without any actual movement. With increased stimulation, patients falsely believed they *had* moved. Curiously, when surgeons stimulated a different association area near the motor cortex in the frontal lobes, the patients did move but had no awareness of doing so (Desmurget et al., 2009). These head-scratching findings suggest that our perception of moving flows

not from the movement itself, but rather from our intention and the results we expected.

On the underside of the right temporal lobe, another association area enables us to recognize faces. If a stroke or head injury destroyed this area of your brain, you would still be able to describe facial features and to recognize someone's gender and approximate age, yet be strangely unable to identify the person as, say, Taylor Swift, or even your grandmother.

Nevertheless, to reemphasize, we should be wary of using pictures of brain “hot spots” to create a new phrenology that locates complex functions in precise brain areas (Beck, 2010; Shimamura, 2010; Uttal, 2001). During a complex task, a brain scan shows many islands of brain activity working together—some running automatically in the background, and others under conscious control (Chein & Schneider, 2012). Your memory, language, and attention result from the synchronized activity among distinct brain areas and neural networks (Knight, 2007). Ditto for religious experience. More than 40 distinct brain regions become active in different religious states, such as prayer and meditation, indicating that there is no simple “God spot” (Fingelkurts & Fingelkurts, 2009). *The point to remember:* Our mental experiences arise from coordinated brain activity.

Check your understanding of the parts of the brain by engaging online with **Concept Practice: Brain Areas Within the Head.**

RETRIEVAL PRACTICE

RP-20 Why are association areas important?

ANSWER: Association areas are involved in higher mental functions—interpreting, integrating, and acting on information processed in other areas.

Responses to Damage

LOQ

2-13 To what extent can a damaged brain reorganize itself, and what is neurogenesis?

Earlier, we learned about the brain's *plasticity*—how our brain adapts to new situations. What happens when we experience mishaps, big and little? Let's explore the brain's ability to modify itself after damage.

Most brain-damage effects can be traced to two hard facts: (1) Severed brain and spinal cord neurons, unlike cut skin, usually do not regenerate. (If your spinal cord were severed, you would probably be permanently paralyzed.) And (2) some brain functions seem preassigned to specific areas. One newborn who suffered damage to temporal lobe facial recognition areas was never able to recognize faces (Farah et al., 2000). But there is good news: Some neural tissue can *reorganize* in response to damage.

Plasticity may also occur after serious damage, especially in young children (Kolb, 1989; see also [FIGURE 2.27](#)). *Constraint-induced therapy* aims to rewire brains and improve the dexterity of a brain-damaged child or even an adult stroke victim (Taub, 2004). By restraining a fully functioning limb, therapists force patients to use the “bad” hand or leg, gradually reprogramming the brain. One stroke victim, a surgeon in his fifties, was put to work cleaning tables, with his good arm and hand restrained. Slowly, the bad arm recovered its skills. As damaged-brain functions migrated to other brain regions, he gradually learned to write again and even to play tennis (Doidge, 2007).

Joe McNally/Joe McNally Photography/Getty Images

FIGURE 2.27 Brain work is child's play

This 6-year-old had surgery to end her life-threatening seizures. Although most of an entire hemisphere was removed (see MRI of hemispherectomy above), her remaining hemisphere compensated by putting other areas to work. One Johns Hopkins medical team reflected on the child hemispherectomies they had performed. Although use of the opposite arm was compromised, the team reported being “awed” by

how well the children had retained their memory, personality, and humor (Vining et al., 1997). The younger the child, the greater the chance that the remaining hemisphere can take over the functions of the one that was surgically removed (Choi, 2008; Danelli et al., 2013).

The brain's plasticity is good news for those blind or deaf. Blindness or deafness makes unused brain areas available for other uses (Amedi et al., 2005). If a blind person uses one finger to read Braille, the brain area dedicated to that finger expands as the sense of touch invades the visual cortex that normally helps people see (Barinaga, 1992; Sadato et al., 1996). Plasticity also helps explain why some studies have found that deaf people who learned sign language before another language have enhanced peripheral and motion-detection vision (Bosworth & Dobkins, 1999; Shiell et al., 2014). In deaf people whose native language is sign, the temporal lobe area normally dedicated to hearing waits in vain for stimulation. Finally, it looks for other signals to process, such as those from the visual system.

Similar reassignment may occur when disease or damage frees up other brain areas normally dedicated to specific functions. If a slow-growing left hemisphere tumor disrupts language (which resides mostly in the left hemisphere), the right hemisphere may compensate (Thiel et al., 2006). If a finger is amputated, the somatosensory cortex that received its input will begin to receive input from the adjacent fingers, which then become more sensitive (Oelschläger et al., 2014). So what do you suppose was the sexual intercourse experience of one patient whose lower leg had been amputated? “I actually experience my orgasm in my [phantom] foot. [Note that in [Figure 2.21](#), the toes region is adjacent to the genitals.] And there it's much bigger than it used to be because it's no longer just confined to my genitals” (Ramachandran & Blakeslee, 1998, [p. 36](#)).

Although the brain often attempts self-repair by reorganizing existing tissue, it sometimes attempts to mend itself through [neurogenesis](#)—producing new neurons. Researchers have found baby neurons deep in the brains of adult mice, birds, monkeys, and humans (He & Jin, 2016; Jessberger et al., 2008). These neurons may then migrate elsewhere and form connections with neighboring neurons (Aimone et al., 2010; Egeland et al., 2015; Gould, 2007).

neurogenesis the formation of new neurons.

Cold War nuclear tests between 1945 and 1963 oddly later enabled scientists to confirm the birth of new brain neurons. The blasts released radioactive carbon isotopes, which, for those exposed, carbon-dated neurons in the hippocampus, a brain center crucial to memory formation. By detecting neurons birthed since then, researchers discovered that 700 new hippocampus neurons are born daily, making nearly a 2 percent annual turnover rate (Kempermann, 2013; Spalding et al., 2013). Our bombs taught us something about our brains.

Master stem cells that can develop into any type of brain cell have also been discovered in the human embryo. If mass-produced in a lab and injected into a damaged brain, might neural stem cells turn themselves into replacements for lost brain cells? Researchers at universities and biotech companies continue to break new ground on how to produce stem cells that resemble functioning human neurons (Lu et al., 2016; Paşca et al., 2015). Such stem cell research not only helps treat the diseased or damaged brain, but also aids understanding of brain development, memory, and other basic psychological processes (Mariani et al., 2012; Sun et al., 2015; Zhang et al., 2016). Might surgeons someday be able to rebuild damaged brains, much as we reseed damaged lawns? Stay tuned. In the meantime, we can all benefit from natural promoters of neurogenesis, such as exercise, sex, sleep, and nonstressful but stimulating environments (Iso et al., 2007; Leuner et al., 2010; Pereira et al., 2007; Sexton et al., 2016; Stranahan et al., 2006).

The Divided Brain

LOQ **2-14** What do split brains reveal about the functions of our two brain hemispheres?

Our brain's look-alike left and right hemispheres serve differing functions. This *lateralization* is apparent after brain damage. Research spanning more than a century has shown that left hemisphere accidents, strokes, and tumors can impair reading, writing, speaking, arithmetic reasoning, and

understanding. Similar right hemisphere damage has less visibly dramatic effects. Does this mean that the right hemisphere is just along for the ride? Many believed this was the case until the 1960s, when a fascinating chapter in psychology's history began to unfold: Researchers found that the “minor” right hemisphere was not so limited after all.

Splitting the Brain

In 1961, Los Angeles neurosurgeons Philip Vogel and Joseph Bogen speculated that major epileptic seizures were caused by an amplification of abnormal brain activity bouncing back and forth between the two cerebral hemispheres, which work together as a whole system. If so, they wondered, could they end this biological tennis match by severing the [corpus callosum](#), the wide band of axon fibers connecting the two hemispheres and carrying messages between them (see [FIGURE 2.28](#))? Vogel and Bogen knew that psychologists Roger Sperry, Ronald Myers, and Michael Gazzaniga had divided cats' and monkeys' brains in this manner, with no serious ill effects.

corpus callosum [KOR-pus kah-LOW-sum] the large band of neural fibers connecting the two brain hemispheres and carrying messages between them.

FIGURE 2.28 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Martin M. Rotker/Science Source; Dr. Patric Hagmann/CHUV, UNIL, Lausanne, Switzerland

FIGURE 2.28 The corpus callosum

This large band of neural fibers connects the two brain hemispheres. To photograph the half brain at left, a surgeon separated the hemispheres by cutting through the corpus callosum (see blue arrow) and lower brain regions. The high-resolution diffusion spectrum image on the right,

showing a top-facing brain from above, reveals brain neural networks within the two hemispheres, and the corpus callosum neural bridge between them.

So the surgeons operated. The result? The seizures all but disappeared. The patients with these [split brains](#) were surprisingly normal, their personality and intellect hardly affected. Waking from surgery, one even joked that he had a “splitting headache” (Gazzaniga, 1967). By sharing their experiences, these patients have greatly expanded our understanding of interactions between the intact brain’s two hemispheres.

split brain a condition resulting from surgery that isolates the brain’s two hemispheres by cutting the fibers (mainly those of the corpus callosum) connecting them.

To appreciate these findings, we need to focus for a minute on the peculiar nature of our visual wiring, illustrated in [FIGURE 2.29](#). Note that each eye receives sensory information from the entire visual field. But in each eye, information from the left half of your field of vision goes to your right hemisphere, and information from the right half of your visual field goes to your left hemisphere, which usually controls speech. Information received by either hemisphere is quickly transmitted to the other across the corpus callosum. In a person with a severed corpus callosum, this information-sharing does not take place.

FIGURE 2.29 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 2.29 The information highway from eye to brain

“Do not let your left hand know what your right hand is doing.”

Matthew 6:3

Knowing these facts, Sperry and Gazzaniga could send information to a patient's left or right hemisphere. As the person stared at a spot, they flashed a stimulus to its right or left. They could do this with you, too, but in your intact brain, the hemisphere receiving the information would instantly pass the news to the other side. Because the split-brain surgery had cut the communication lines between the hemispheres, the researchers could, with these patients, quiz each hemisphere separately.

In an early experiment, Gazzaniga (1967) asked split-brain patients to stare at a dot as he flashed HE·ART on a screen ([FIGURE 2.30](#)). Thus, HE appeared in their left visual field (which transmits to the right hemisphere) and ART in the right field (which transmits to the left hemisphere). When he then asked them to *say* what they had seen, the patients reported that they had seen ART. But when asked to *point* to the word they had seen, they were startled when their left hand (controlled by the right hemisphere) pointed to HE. Given an opportunity to express itself, each hemisphere indicated what it had seen. The right hemisphere (controlling the left hand) intuitively knew what it could not verbally report.

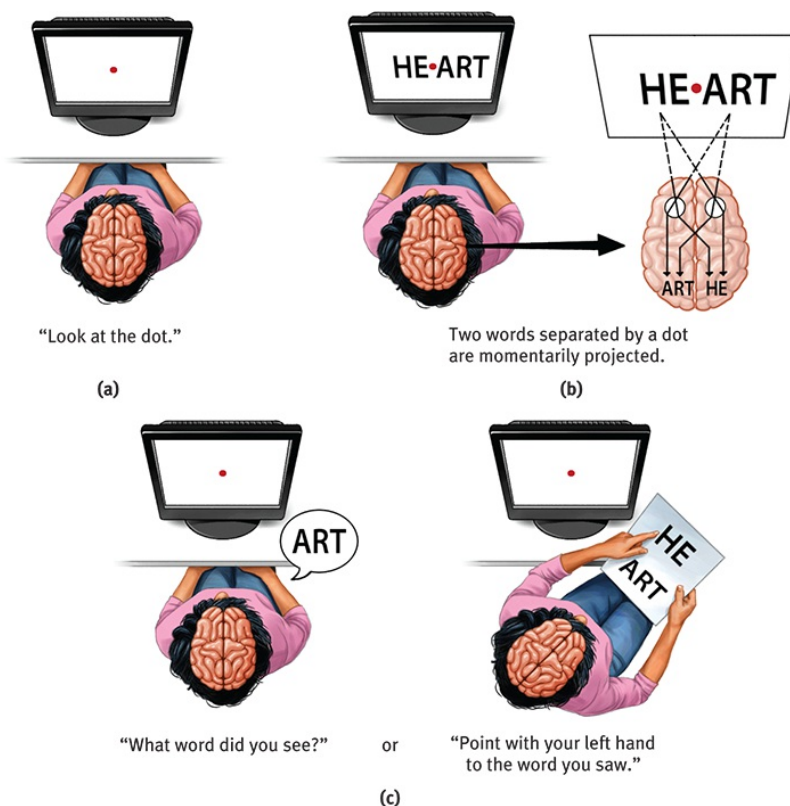

FIGURE 2.30 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.30 One skull, two minds

When an experimenter flashes the word HEART across the visual field, a woman with a split brain verbally reports seeing the portion of the word transmitted to her left hemisphere. However, if asked to indicate with her left hand what she saw, she points to the portion of the word transmitted to her right hemisphere. (From Gazzaniga, 1983.)

When a picture of a spoon was flashed to their right hemisphere, the patients could not *say* what they had viewed. But when asked to *identify* what they had viewed by feeling an assortment of hidden objects with their left hand, they readily selected the spoon. If the experimenter said, “Correct!” the patient might reply, “What? Correct? How could I possibly pick out the correct object when I don’t know what I saw?” It is, of course, the left hemisphere doing the talking here, bewildered by what the nonverbal right hemisphere knows.

A few people who have had split-brain surgery have been for a time bothered by the unruly independence of their left hand. It seemed the left hand truly didn’t know what the right hand was doing. The left hand might unbutton a shirt while the right hand buttoned it, or put grocery store items back on the shelf after the right hand put them in the cart. It was as if each hemisphere was thinking “I’ve half a mind to wear my green (blue) shirt today.” Indeed, said Sperry (1964), split-brain surgery leaves people “with two separate minds.” With a split brain, both hemispheres can comprehend and follow an instruction to copy—*simultaneously*—different figures with the left and right hands (Franz et al., 2000; see also [FIGURE 2.31](#)). (Reading these reports, can you imagine a patient enjoying a solitary game of “rock, paper, scissors”—left versus right hand?)

FIGURE 2.31 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 2.31 Try this!

People who have had split-brain surgery can simultaneously draw two different shapes.

When the “two minds” are at odds, the left hemisphere does mental gymnastics to rationalize reactions it does not understand. If a patient follows an order (“Walk”) sent to the right hemisphere, a strange thing happens. The left hemisphere, unaware of the order, doesn’t know why the patient begins walking. But if asked, the patient doesn’t reply, “I don’t know.” Instead, the left hemisphere improvises—“I’m going into the house to get a Coke.” Gazzaniga (1988), who described these patients as “the most fascinating people on earth,” realized that the conscious left hemisphere resembles an interpreter that instantly constructs explanations. The brain, he concluded, often runs on autopilot; it acts first and then explains itself.

RETRIEVAL PRACTICE

RP-21 (1) If we flash a red light to the right hemisphere of a person with a split brain, and flash a green light to the left hemisphere, will each observe its own color? (2) Will the person be aware that the colors differ? (3) What will the person verbally report seeing?

ANSWER: 1. yes, 2. no, 3. green

Have you ever been asked if you are “left-brained” or “right-brained”? Consider this popular misconception by engaging online with **Immersive Learning: How Would You Know If People Can Be “Left-Brained” or “Right-Brained”?**

Right-Left Differences in the Intact Brain

So, what about the 99.99+ percent of us with undivided brains? Does each of *our* hemispheres also perform distinct functions? The short answer is *Yes*. When a person performs a *perceptual* task, a brain scan often reveals increased activity (brain waves, bloodflow, and glucose consumption) in the *right* hemisphere. When the person speaks or does a math calculation, activity usually increases in the *left* hemisphere.

A dramatic demonstration of hemispheric specialization happens before some types of brain surgery. To locate the patient’s language centers, the surgeon injects a sedative into the neck artery feeding blood to the left hemisphere, which usually controls speech. Before the injection, the patient is lying down, arms in the air, chatting with the doctor. Can you predict what probably happens when the drug puts the left hemisphere to sleep? Within seconds, the person’s right arm falls limp. If the left hemisphere is controlling language, the patient will be speechless until the drug wears off. If the drug is injected into the artery to the right hemisphere, the left arm will fall limp, but the person will still be able to speak.

To the brain, language is language, whether spoken or signed. Just as hearing people usually use the left hemisphere to process spoken language, deaf people use the left hemisphere to process sign language (Corina et al., 1992; Hickok et al., 2001). Thus, a left hemisphere stroke disrupts a deaf person’s signing, much as it would disrupt a hearing person’s speaking (Corina, 1998).

Brain scans show that, like humans, dogs usually process words with their left hemisphere and intonation with a right hemisphere region. One study demonstrated that giving praise was ineffective if what the dogs heard didn’t match *how* it was spoken (Andics et al., 2016).

Although the left hemisphere is skilled at making quick, literal interpretations of language, the right hemisphere

- *excels in making inferences* (Beeman & Chiarello, 1998; Bowden & Beeman, 1998; Mason & Just, 2004). Primed with the flashed word *foot*, the left hemisphere will be especially quick to recognize the closely associated word *heel*. But if given an insight-like problem—“What word goes with *boot*, *summer*, and *ground*?”—the right hemisphere more quickly comes to a reasoned conclusion and recognizes the solution: *camp*. As one patient explained after a right hemisphere stroke, “I understand words, but I’m missing the subtleties.” The right side of the brain is also better than the left at copying drawings, recognizing faces, noticing differences, perceiving emotion, and expressing emotion through the more expressive left side of the face. Right hemisphere damage can greatly disrupt these abilities.
- *helps us modulate our speech* to make meaning clear—as when we say “Let’s eat, Grandpa” instead of “Let’s eat Grandpa” (Heller, 1990).
- *helps orchestrate our self-awareness*. People who suffer partial paralysis will sometimes stubbornly deny their impairment—strangely claiming they can move a paralyzed limb—if the damage is to the right hemisphere (Berti et al., 2005).

Simply looking at the two hemispheres, so alike to the naked eye, who would suppose they each contribute uniquely to the harmony of the whole? Yet a variety of observations—of people with split brains, of people with normal brains, and even of other species’ brains—converge beautifully, leaving little doubt that we have unified brains with specialized parts (Hopkins & Cantalupo 2008; MacNeilage et al., 2009).

For a helpful animated review of this research, see **PsychSim 6: Hemispheric Specialization**.

* * *

In this chapter we have glimpsed an overriding principle: Everything psychological is simultaneously biological. We have focused on how our thoughts, feelings, and actions arise from our specialized yet integrated and

wondrously adaptable brain. In chapters to come, we will further explore the significance of the biological revolution in psychology.

Roz Chast The New Yorker Collection/
The Cartoon Bank

From nineteenth-century phrenology to today's neuroscience, we have come a long way. Yet what is unknown still dwarfs what is known. We can describe the brain. We can learn the functions of its parts. We can study how the parts communicate. But how do we get mind out of meat? How does the electrochemical whir in a hunk of tissue the size of a small cabbage give rise to elation, a creative idea, or that memory of Grandmother?

Much as gas and air can give rise to something different—fire—so also, believed Roger Sperry, does the complex human brain give rise to something different: *consciousness*. The mind, he argued, emerges from the brain's dance of ions, yet is not reducible to it. As neuroscientist Donald MacKay (1978) observed, "[My brain activity] reflects what I am thinking, as [computer] activity reflects the equation it is solving." The mind and brain activities are yoked, he noted, but are complementary and conceptually distinct.

Cells cannot be fully explained by the actions of atoms, nor minds by the activity of cells. Psychology is rooted in biology, which is rooted in chemistry, which is rooted in physics. Yet psychology is more than applied physics. As Jerome Kagan (1998) reminded us, the meaning of the Gettysburg Address is not reducible to neural activity. Sexual love is more than blood flooding to the genitals. Morality and responsibility become

possible when we understand the mind as a “holistic system,” said Sperry (1992). We are not mere jabbering robots. Brains make thoughts. And thoughts change brains.

“All psychological phenomena are caused by the brain, but many are better understood at the level of the mind.”

Tweet from psychologist Steven Pinker, June 10, 2013

The mind seeking to understand the brain—that is indeed among the ultimate scientific challenges. And so it will always be. To paraphrase cosmologist John Barrow, a brain simple enough to be fully understood is too simple to produce a mind able to understand it.

REVIEW The Cerebral Cortex

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009; 2015).

LOQ 2-11 [What four lobes make up the cerebral cortex, and what are the functions of the motor cortex, somatosensory cortex, and association areas?](#)

LOQ 2-12 [Do we really use only 10 percent of our brain?](#)

LOQ 2-13 [To what extent can a damaged brain reorganize itself, and what is neurogenesis?](#)

LOQ 2-14 [What do split brains reveal about the functions of our two brain hemispheres?](#)

TERMS AND CONCEPTS TO REMEMBER

Test yourself on these terms by trying to compose the definition before checking your answers.

[cerebral \[seh-REE-bruhl\] cortex](#), p. 75

[frontal lobes](#), p. 75

[parietal \[puh-RYE-uh-tuhl\] lobes](#), p. 75

[occipital \[ahk-SIP-uh-tuhl\] lobes](#), p. 75

[temporal lobes](#), p. 75

[split brain](#), p. 82

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

If a neurosurgeon stimulated your right motor cortex, you would most likely

- a. see light.
- b. hear a sound.
- c. feel a touch on the right arm.
- d. move your left leg.

How do different neural networks communicate with one another to let you respond when a friend greets you at a party?

Which of the following body regions has the greatest representation in the somatosensory cortex?

- a. Upper arm
- b. Toes
- c. Lips
- d. All regions are equally represented.

Judging and planning are enabled by the _____ lobes.

The “uncommitted” areas that make up about three-fourths of the cerebral cortex are called _____.

The flexible brain’s ability to respond to damage is especially evident in the brains of

- a. split-brain patients.
- b. young adults.
- c. young children.
- d. right-handed people.

An experimenter flashes the word HERON across the visual field of a man whose corpus callosum has been severed. HER is transmitted to his right hemisphere and ON to his left hemisphere. When asked to indicate what he saw, the man says he saw _____ but his left hand points to _____.

Studies of people with split brains and brain scans of those with undivided brains indicate that the left hemisphere excels in

- a. processing language.
- b. visual perceptions.
- c. making inferences.
- d. neurogenesis.

Damage to the brain’s right hemisphere is most likely to reduce a person’s ability to

- a. recite the alphabet rapidly.
- b. make inferences.
- c. understand verbal instructions.
- d. solve arithmetic problems.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Dual Processing: The Two-Track Mind

Sleep and Dreams

Biological Rhythms and Sleep

Why Do We Sleep?

Sleep Deprivation and Sleep Disorders

Dreams

Drugs and Consciousness

Tolerance and Addiction in Substance Use Disorders

THINKING CRITICALLY ABOUT: Tolerance and Addiction

Types of Psychoactive Drugs

Influences on Drug Use

Consciousness can be a funny thing. It offers us weird experiences, as when entering sleep or leaving a dream, and sometimes it leaves us wondering who is really in control. After zoning me [DM] out with nitrous oxide, my dentist tells me to turn my head to the left. My conscious mind resists: “No way,” I silently say. “*You can’t boss me around!*” Whereupon my robotic head, ignoring my conscious mind, turns obligingly under the dentist’s control.

During my noontime pickup basketball games, I am sometimes mildly irritated as my body passes the ball while my conscious mind says, “No, stop! Sarah is going to intercept!” Alas, my body completes the pass. Other times, as psychologist Daniel Wegner (2002) noted in *The Illusion of Conscious Will*, people believe their conscious mind is controlling their actions when it isn’t. In one experiment, two people jointly controlled a computer mouse. Even when their partner (who was actually the experimenter’s accomplice) caused the mouse to stop on a predetermined square, the participants perceived that *they* had caused it to stop there.

Then there are those times when consciousness seems to split. Sometimes, my [ND’s] mind wanders while giving a well-practiced speech. Reading *Green Eggs and Ham* to one of my [DM’s] preschoolers for the umpteenth time, my obliging mouth could say the words while my mind flitted in and out of the story. And if someone drops by my office while I’m typing a sentence, it’s not a problem. My fingers complete their keyboard dance as I strike up a conversation.

What do such experiences reveal? Is a drug-induced dental experience akin to people’s experiences with other *psychoactive drugs* (mood- and perception-altering substances)? Does the mind’s wandering while speaking or typing reveal a split in consciousness? And during sleep, when do those weird dream experiences occur, and why? Before considering these questions and more, let’s ask a fundamental question: What is *consciousness*?

Basic Consciousness Concepts

Every science has concepts so fundamental they are nearly impossible to define. Biologists agree on what is alive but not on precisely what life is. In physics, *matter* and *energy* elude simple definition. To psychologists, consciousness is similarly a fundamental yet slippery concept.

Defining Consciousness

LOQ **LEARNING OBJECTIVE QUESTION** **3-1** What is the place of consciousness in psychology's history?

At its beginning, *psychology* was “the description and explanation of states of consciousness” (Ladd, 1887). But during the first half of the twentieth century, the difficulty of scientifically studying consciousness led many psychologists—including those in the emerging school of *behaviorism* ([Chapter 7](#))—to turn to direct observations of behavior. By the 1960s, psychology had nearly lost consciousness and was defining itself as “the science of behavior.” Consciousness was likened to a car’s speedometer: “It doesn’t make the car go, it just reflects what’s happening” (Seligman, 1991, [p. 24](#)).

“Psychology must discard all reference to consciousness.”

Behaviorist John B. Watson (1913)

After 1960, mental concepts reemerged. Neuroscience advances linked brain activity to sleeping, dreaming, and other mental states. Researchers began studying consciousness altered by drugs, hypnosis, and meditation. (More on hypnosis in [Chapter 6](#) and meditation in [Chapter 12](#).) Psychologists of all persuasions were affirming the importance of *cognition*, or mental processes. Psychology was regaining consciousness.

Most psychologists define **consciousness** as our subjective awareness of ourselves and our environment (Feinberg & Mallatt, 2016):

consciousness our subjective awareness of ourselves and our environment.

- This awareness allows us to assemble information from many sources as we reflect on our past, adapt to our present, and plan for our future. First-year university students think back to their high school years, adjust to the ups and downs of academic life, and look ahead to their life beyond graduation.
- It focuses our attention when we learn a complex concept or behavior. When learning to drive, we focus on the car and the traffic. With practice, driving becomes semiautomatic, freeing us to focus our attention on other things.
- Over time, we flit between different *states of consciousness*, including normal waking awareness and various altered states ([FIGURE 3.1](#)).

Some states occur spontaneously	Daydreaming	Drowsiness	Dreaming
Some are physiologically induced	Hallucinations	Orgasm	Food or oxygen starvation
Some are psychologically induced	Sensory deprivation	Hypnosis	Meditation

FIGURE 3.1 Altered states of consciousness

In addition to normal, waking awareness, consciousness comes to us in altered states, including daydreaming, sleeping, drug-induced hallucinating, and meditating.

Today's science explores the biology of consciousness. Evolutionary psychologists presume that consciousness offers a reproductive advantage (Barash, 2006; Murdik et al., 2011). Consciousness helps us cope with novel situations and act in our long-term interests, rather than merely seeking short-term pleasure and avoiding pain. Consciousness also promotes our survival by anticipating how we seem to others and helping us read their minds: "He looks really angry! I'd better run!"

Such explanations still leave us with what researchers call the "hard problem": How do brain cells jabbering to one another create our awareness of the taste of a taco, the idea of infinity, the feeling of fright? The question of how consciousness arises from the material brain is one of life's deepest mysteries.

Studying Consciousness

Cognitive Neuroscience

Scientists assume, in the words of neuroscientist Marvin Minsky (1986, [p. 287](#)), that “the mind is what the brain does.” We just don’t know *how* it does it. Even with all the world’s technology, we still don’t have a clue *how* to make a conscious robot. Yet today’s [cognitive neuroscience](#)—the interdisciplinary study of the brain activity linked with our mental processes—is relating specific brain states to conscious experiences (Koch et al., 2016).

cognitive neuroscience the interdisciplinary study of the brain activity linked with cognition (including perception, thinking, memory, and language).

A stunning demonstration of consciousness appeared in brain scans of a noncommunicative patient—a 23-year-old woman who had been in a car accident and showed no outward signs of conscious awareness (Owen, 2014; Owen et al., 2006). When researchers asked her to *imagine* playing tennis, fMRI scans revealed activity in a brain area that normally controls arm and leg movements ([FIGURE 3.2](#)). Even in a motionless body, the researchers concluded, the brain—and the mind—may still be active. A follow-up analysis of 42 behaviorally unresponsive patients revealed 13 more who also showed meaningful though diminished brain responses to questions (Stender et al., 2014).

FIGURE 3.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
 Courtesy of Adrian M. Owen, the Brain and Mind Institute,
 Western University

FIGURE 3.2 Evidence of awareness?

When asked to imagine playing tennis or navigating her home, a noncommunicative patient's brain (top) exhibited activity similar to a healthy person's brain (bottom). Researchers wonder if such fMRI scans might enable a “conversation” with some unresponsive patients, by instructing them, for example, to answer *yes* to a question by imagining playing tennis (top and bottom left), and *no* by imagining walking around their home (top and bottom right).

Many cognitive neuroscientists are exploring and mapping the conscious functions of the cortex. Based on your cortical activation patterns, they can now, in limited ways, read your mind (Bor, 2010). They could, for example, tell which of 10 similar objects (hammer, drill, and so forth) you were viewing (Shinkareva et al., 2008).

Conscious experience arises from synchronized activity across the brain (Chennu et al., 2014; Gaillard et al., 2009; Schurger et al., 2010). If a stimulus activates enough brain-wide coordinated neural activity—as strong signals in one brain area trigger activity elsewhere—it crosses a threshold for

consciousness. A weaker stimulus—perhaps a word flashed too briefly to be consciously perceived—may trigger localized visual cortex activity that quickly fades. A stronger stimulus will engage other brain areas, such as those involved with language, attention, and memory. Such reverberating activity (detected by brain scans) is a telltale sign of conscious awareness (Boly et al., 2011; Silverstein et al., 2015). For example, awareness of your body involves communication between several brain areas (Blanke, 2012; Olivé et al., 2015). How the synchronized activity produces awareness—how matter makes mind—remains a mystery.

RETRIEVAL PRACTICE

RP-1 Those working in the interdisciplinary field called _____ study the brain activity associated with the mental processes of perception, thinking, memory, and language.

ANSWER: cognitive neuroscience

Selective Attention

LOQ 3-2 How does selective attention direct our perceptions?

Through [selective attention](#), our awareness focuses, like a flashlight beam, on a minute aspect of all that we experience. We may think we can fully attend to a conversation or a class lecture while checking and returning text messages. Actually, our consciousness focuses on but one thing at a time.

selective attention the focusing of conscious awareness on a particular stimulus.

By one estimate, our five senses take in 11,000,000 bits of information per second, of which we consciously process about 40 (Wilson, 2002). Yet our mind's unconscious track intuitively makes great use of the other 10,999,960 bits.

What captures our limited attention? Things we deem important. A classic example of selective attention is the *cocktail party effect*—your ability to attend to one voice among a sea of other voices. But what happens when another voice speaks your name? Your cognitive radar, operating on your mind’s other track (and in your right frontal cortex), instantly brings that unattended voice into consciousness (Demeter & Woldorff, 2016). This effect might have prevented an embarrassing and dangerous situation in 2009, when two Northwest Airlines pilots “lost track of time.” Focused on their laptops and in conversation, they ignored alarmed air traffic controllers’ attempts to reach them and overflowed their Minneapolis destination by 150 miles. If only the controllers had known and spoken the pilots’ names.

Selective Attention and Accidents

Have you, like 60 percent of American drivers, read or sent a text message or viewed a phone map while driving in the last month (Glicklich, 2016)? Doing so causes your selective attention to shift back and forth between the road and its electronic competition. Indeed, our attention shifts more often than we realize. One study left people in a room for 28 minutes with full Internet and television access. On average, they guessed their attention switched 15 times. But they were not even close. Eye-tracking revealed eight times that many attentional switches—120 in all (Brasel & Gips, 2011).

"I wasn't texting. I was building this ship in a bottle."

The New Yorker Collection, 2009, Robert Leighton, from cartoonbank.com.
All Rights Reserved.

Rapid toggling between activities is today’s great enemy of sustained,

focused attention. When we switch attentional gears, especially when we shift to complex tasks like noticing and avoiding cars around us, we pay a toll—a slight and sometimes fatal delay in coping (Rubenstein et al., 2001). When a driver attends to a conversation, activity in brain areas vital to driving decreases an average of 37 percent (Just et al., 2008).

Texting or phone chatting—something 1 in 4 drivers admit doing—accompanies about 28 percent of traffic accidents (NSC, 2010; Pew, 2011). One video cam study of teen drivers found that driver distraction from passengers or phones occurred right before 58 percent of their crashes (AAA, 2015). Talking with passengers makes the risk of an accident 1.6 times higher than normal. Talking on a cell phone (even with a hands-free set) makes the risk 4 times higher than normal—equal to the risk of drunk driving (McEvoy et al., 2005, 2007). And while talking is distracting, texting wins the danger game. One 18-month video cam study tracked the driving habits of long-haul truckers. When they were texting, their risk of a collision increased 23 times (Olson et al., 2009)! Many European countries and most American states and Canadian provinces now ban texting while driving (CBC News, 2014; Rosenthal, 2009). So the next time you're behind the wheel, put the brakes on your texts. Your passengers and fellow drivers will thank you.

Watch the thought-provoking **Video: Automatic Skills—Disrupting a Pilot's Performance**.

Inattentional Blindness

At the level of conscious awareness, we are “blind” to all but a tiny sliver of visual stimuli. Ulric Neisser (1979) and Robert Becklen and Daniel Cervone (1983) demonstrated this [inattentional blindness](#) dramatically by showing people a one-minute video of basketball players, three in black shirts and three in white shirts, tossing a ball. Researchers told the viewers to press a key every time they saw a black-shirted player pass the ball. Most viewers were so intent on their task that they failed to notice a young woman carrying an umbrella saunter across the screen midway through the video ([FIGURE 3.3](#)). Watching a replay of the video, viewers were astonished to see her (Mack & Rock, 2000). This inattentional blindness is a by-product of what we are really good at: focusing attention on some part of our environment.

inattention blindness failing to see visible objects when our attention is directed elsewhere.

FIGURE 3.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.3 Inattention blindness

Viewers who were attending to basketball tosses among the black-shirted players usually failed to notice the umbrella-toting woman sauntering across the screen (Neisser, 1979).

Reprinted with permission of Bill Whitehead

In a repeat of the experiment, smart-aleck researchers sent a gorilla-suited assistant through the swirl of players (Simons & Chabris, 1999). During its 5- to 9-second cameo appearance, the gorilla paused and thumped its chest. But the gorilla did not steal the show: Half the conscientious pass-counting viewers failed to see it. Psychologists like to have fun, and have continued to do so with invisible gorillas. One study of “inattentional deafness” delivered, separately to each ear, a recording of men talking and of women talking. When volunteers were assigned to pay attention to the women, 70 percent failed to hear one of the men saying, over and over for 19 seconds, “I’m a gorilla” (Dalton & Fraenkel, 2012). And when 24 radiologists were looking for cancer nodules in lung scans, 20 of them missed the gorilla superimposed in the upper right of [FIGURE 3.4](#)—though, to their credit, their focus enabled them to spot the much tinier cancer tissue (Drew et al., 2013). The serious point to these seeming psychological pranks: Attention is powerfully selective. Your conscious mind is in one place at a time.

FIGURE 3.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Trafton Drew

FIGURE 3.4 The invisible gorilla strikes again

When repeatedly exposed to the gorilla in the upper right while searching for much tinier cancer nodules, radiologists usually failed to see it (Drew et al., 2013).

For more on the limits of our attention, engage online with **Concept Practice: Selective Attention and Multitasking**.

Given that most people miss someone in a gorilla suit while their attention is riveted elsewhere, imagine the fun that others can have by manipulating our selective attention. Misdirect people's attention and they will miss the hand slipping into the pocket. "Every time you perform a magic trick, you're engaging in experimental psychology," says magician Teller, a master of mind-messing methods (2009). Clever thieves know this, too. One Swedish psychologist was surprised in Stockholm by a woman exposing her naked body; only later did he realize that he had been pickpocketed, outwitted by thieves who understood the limits of our selective attention (Gallace, 2012).

In other experiments, people exhibited a form of inattention blindness called **change blindness**. In laboratory experiments, viewers failed to notice that, after a brief visual interruption, a big Coke bottle had disappeared, a railing had risen, clothing had changed color—and construction workers had changed places (**FIGURE 3.5**) (Chabris & Simons, 2010; Resnick et al., 1997). Out of sight, out of mind.

FIGURE 3.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.5 Change blindness

While a man (in red) provides directions to a construction worker, two experimenters rudely pass between them carrying a door. During this interruption, the original worker switches places with another person wearing different-colored clothing. Most people, focused on their direction giving, do not notice the switch (Simons & Levin, 1998).

change blindness failing to notice changes in the environment; a form of

inattention blindness.

“Has a generation of texters, surfers, and twitterers evolved the enviable ability to process multiple streams of novel information in parallel? Most cognitive psychologists doubt it.”

Steven Pinker, “Not at All,” 2010

 For more on change blindness, watch the 3-minute **Video: Visual Attention**.

A Swedish research team discovered that people’s blindness extends to their own choices. Petter Johansson and his colleagues (2005, 2014) showed 120 volunteers two female faces and asked which face was more attractive. After putting both photos face down, they handed viewers the one chosen and invited them to explain why they preferred it. But on 3 of 15 occasions, the researchers secretly switched the photos—showing viewers the face they had *not* chosen ([FIGURE 3.6](#)). People noticed the switch only 13 percent of the time, and readily explained why they preferred the face they had actually rejected. “I chose her because she smiled,” said one person (after picking the solemn-faced one). Asked later whether they would notice such a switch in a “hypothetical experiment,” 84 percent insisted they would.

FIGURE 3.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Mark Hanlon

FIGURE 3.6 Choice blindness

Pranksters Petter Johansson, Lars Hall, and others (2005) invited people to choose preferred faces. On occasion, they asked people to explain their preference for the *unchosen* photo. Most—failing to notice the switch—readily did so.

Change *deafness* can also occur. In one experiment, 40 percent of people who focused on repeating a list of words that someone spoke failed to notice a change in the person speaking (Vitevitch, 2003). In two follow-up phone interview experiments, only 2 of 40 people noticed that the female interviewer changed after the third question—a change that was noticeable if people were forewarned of a possible interviewer change (Fenn et al., 2011). Some stimuli, however, are so powerful, so strikingly distinct, that we experience *popout*. For example, when the female phone interviewer changed to a male interviewer, virtually everyone noticed.

RETRIEVAL PRACTICE

RP-2 Explain three attentional principles that magicians may use to fool us.

ANSWER: Our *selective attention* allows us to focus on only a limited portion of our surroundings. *Inattentional blindness* explains why we don't perceive some things when we are distracted. And *change blindness* happens when we fail to notice a relatively unimportant change in our environment. All three principles help magicians fool us, as they direct our attention elsewhere to perform their tricks.

Dual Processing: The Two-Track Mind

LOQ 3-3 What is the *dual processing* being revealed by today's cognitive neuroscience?

Discovering which brain region becomes active with a particular conscious experience strikes many people as interesting, but not mind-blowing. (If everything psychological is simultaneously biological, then our ideas,

emotions, and spirituality must all, somehow, be embodied.) What is mind-blowing to many of us is the growing evidence that we have, so to speak, two minds, each supported by its own neural equipment.

At any moment, we are aware of little more than what's on the screen of our consciousness. But beneath the surface, unconscious information processing occurs simultaneously on many parallel tracks. When we look at a bird flying, we are consciously aware of the result of our cognitive processing ("It's a hummingbird!") but not of our subprocessing of the bird's color, form, movement, and distance. One of the grand ideas of recent cognitive neuroscience is that much of our brain work occurs off stage, out of sight. Perception, memory, thinking, language, and attitudes all operate on two levels—a conscious, deliberate "high road" and an unconscious, automatic "low road." The high road is reflective, the low road intuitive (Evans & Stanovich, 2013; Kahneman, 2011). Today's researchers call this [dual processing](#). We know more than we know we know.

dual processing the principle that information is often simultaneously processed on separate conscious and unconscious tracks.

If you are a driver, consider how you move to the right lane. Drivers know this unconsciously but cannot accurately explain it (Eagleman, 2011). Most say they would bank to the right, then straighten out—a procedure that would actually steer them off the road. In reality, an experienced driver, after moving right, automatically reverses the steering wheel just as far to the left of center, and only then returns to the center position. The lesson: The human brain is a device for converting conscious into unconscious knowledge.

Or consider this story, which illustrates how science can be stranger than science fiction. During my sojourns at Scotland's University of St Andrews, I [DM] came to know cognitive neuroscientists David Milner and Melvyn Goodale (2008). They studied a local woman, D. F., who suffered brain damage when overcome by carbon monoxide, leaving her unable to recognize and discriminate objects visually. Consciously, D. F. could see nothing. Yet she exhibited [blindsight](#)—she acted as though she could see. Asked to slip a postcard into a vertical or horizontal mail slot, she could do so without error. Asked the width of a block in front of her, she was at a loss,

but she could grasp it with just the right finger–thumb distance. Likewise, if your right and left eyes view different scenes, you will only be consciously aware of one at a time. Yet you will display some blindsight awareness of the other (Baker & Cass, 2013).

blindsight a condition in which a person can respond to a visual stimulus without consciously experiencing it.

How could this be? Don't we have one visual system? Goodale and Milner knew from animal research that the eye sends information simultaneously to different brain areas, which support different tasks (Weiskrantz, 2009, 2010). Sure enough, a scan of D. F.'s brain activity revealed normal activity in the area concerned with reaching for, grasping, and navigating objects, but damage in the area concerned with consciously recognizing objects.¹ (See another example in [FIGURE 3.7.](#))

FIGURE 3.7 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 3.7 When the blind can “see”

In this compelling demonstration of blindsight and the two-track mind, researcher Lawrence Weiskrantz trailed a blindsight patient down a cluttered hallway. Although told the hallway was empty, the patient meandered around all the obstacles without any awareness of them.

How strangely intricate is this thing we call vision, conclude Goodale and Milner in their aptly titled book, *Sight Unseen*. We may think of our vision as a single system that controls our visually guided actions. Actually, it is a dual-processing system (Foley et al., 2015). A *visual perception track* enables us “to think about the world”—to recognize things and to plan future actions. A *visual action track* guides our moment-to-moment movements.

The dual-track mind also appeared in a patient who lost all of his left visual cortex, leaving him blind to objects and faces presented on the right side of his field of vision. He nevertheless could sense the emotion expressed in faces, which he did not consciously perceive (De Gelder, 2010). The same is true of normally sighted people whose visual cortex has been disabled with magnetic stimulation. Such findings suggest that brain areas below the cortex are processing emotion-related information.

People often have trouble accepting that much of our everyday thinking, feeling, and acting operates outside our conscious awareness (Bargh & Chartrand, 1999). Some “80 to 90 percent of what we do is unconscious,” says Nobel laureate and memory expert Eric Kandel (2008). We are understandably inclined to believe that our intentions and deliberate choices rule our lives. But they don’t. Consciousness, though enabling us to exert voluntary control and to communicate our mental states to others, is but the tip of the information-processing iceberg. Just ask the volunteers who chose a card after watching a magician shuffle through the deck (Olson et al., 2015b). In nearly every case, the magician swayed participants’ decisions by subtly allowing one card to show for longer—but 91 percent of participants believed they had made the choice on their own. Being intensely focused on an activity (such as reading this chapter, we’d love to think) increases your total brain activity no more than 5 percent above its baseline rate. And even when you rest, activity whirls inside your head (Raichle, 2010).

Here’s another weird (and provocative) finding: Experiments show that when you move your wrist at will, you consciously experience the decision to move it about 0.2 seconds before the actual movement (Libet, 1985, 2004). No surprise there. But your brain waves jump about 0.35 seconds before you

consciously perceive your decision to move ([FIGURE 3.8](#))! The startling conclusion: Consciousness sometimes arrives late to the decision-making party.

FIGURE 3.8 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 3.8 Is the brain ahead of the mind?

In this study, volunteers watched a computer clock sweep through a full revolution every 2.56 seconds. They noted the time when they decided to move their wrist. About one-third of a second before that decision, their brain-wave activity jumped, indicating a *readiness potential* to move. Watching a slow-motion replay, the researchers could predict when a person was about to decide to move (following which, the wrist did move) (Libet, 1985, 2004). Skeptics, however, question the clock measurement procedure (Miller et al., 2011).

That inference has triggered more research and much debate. Does our brain really make decisions before we know about them? If so, is free will an illusion? Using fMRI scans, EEG recordings, or implanted electrodes, some studies seem to confirm that brain activity precedes—and helps predict—people’s decisions to press a button or to choose a card in a simplified poker game (Carter et al., 2012; Fried et al., 2011; Soon et al., 2008). Perhaps, as an everyday example of consciousness arriving after “most of the work has already been done” (Haynes, 2008), you can recall lying in bed in the morning, knowing you should get up. The bed feels good, so you linger . . . until suddenly you observe yourself throwing back the covers and sitting up. Did your brain decide to get up a microsecond before announcing the decision to your mind?

To think further about the implications of these provocative findings for our understanding of free will and decision making, visit **PsychSim 6: Who's in Charge?**

However, other studies indicate that brain activity continuously ebbs and flows, including during the experiments' predecision phase—regardless of whether the decision is made and executed (Parkinson & Haggard, 2015; Schurger et al., 2012). The actual decision to move occurs when the brain activity crosses a threshold, which coincides with the average “time of awareness of intention to move” (about 0.15 second before the movement). This view sees the mind's decision and the brain's activity, like a computer's problem solving and its electronic activity, as simultaneous and parallel.

Unconscious parallel processing is faster than conscious sequential processing, but both are essential. [Parallel processing](#) enables your mind to take care of routine business. [Sequential processing](#) is best for solving new problems, which requires our focused attention on one thing at a time. Try this: If you are right-handed, move your right foot in a smooth counterclockwise circle and write the number 3 repeatedly with your right hand—at the same time. Try something equally difficult: Tap a steady beat three times with your left hand while tapping four times with your right hand. Both tasks require conscious attention, which can be in only one place at a time. If time is nature's way of keeping everything from happening at once, then consciousness is nature's way of keeping us from thinking and doing everything at once.

parallel processing processing many aspects of a problem simultaneously; generally used to process well-learned information or to solve easy problems.

sequential processing processing one aspect of a problem at a time; generally used to process new information or to solve difficult problems.

Running on automatic pilot allows our consciousness—our mind's CEO—to monitor the whole system and deal with new challenges, while neural assistants automatically take care of routine business. A skilled tennis player's brain and body respond automatically to an oncoming serve before

becoming consciously aware of the ball's trajectory (which takes about three-tenths of a second). Ditto for other skilled athletes, for whom action precedes awareness. *The bottom line:* In everyday life, we mostly function like an automatic camera, but with a manual (conscious) override.

Great myths often engage simple pairs: good Cinderella and the evil stepmother, the slow Tortoise and fast Hare, the logical Sherlock Holmes and emotional Dr. Watson. The myths have enduring power because they express our human reality. Dualities are us.

RETRIEVAL PRACTICE

RP-3 What are the mind's two tracks, and what is *dual processing*?

ANSWER: Our mind simultaneously processes information on a conscious track and an unconscious track (dual processing) as we organize and interpret information.

REVIEW Basic Consciousness Concepts

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Failure to see visible objects because our attention is occupied elsewhere is called _____.

We register and react to stimuli outside of our awareness by means of _____ processing. When we devote deliberate attention to stimuli, we use _____ processing.

Inattentional blindness is a product of our _____ attention.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Sleep and Dreams

LOQ 3-4 What is *sleep*?

Sleep—the irresistible tempter to whom we inevitably succumb. Sleep—the equalizer of presidents and peasants. Sleep—sweet, renewing, mysterious sleep. While sleeping, you may feel “dead to the world,” but you are not. Even when you are deeply asleep, your perceptual window is open a crack. You move around on your bed, but you manage not to fall out. Although the roar of my [ND’s] neighborhood garbage truck leaves me undisturbed, my baby’s cry will shatter my sleep. The sound of your name can also cause your unconscious body to perk up. EEG recordings confirm that the brain’s auditory cortex responds to sound stimuli even during sleep (Kutas, 1990). And when you sleep, as when awake, you process most information outside your conscious awareness.

sleep a periodic, natural loss of consciousness—as distinct from unconsciousness resulting from a coma, general anesthesia, or hibernation. (Adapted from Dement, 1999.)

“I love to sleep. Do you? Isn’t it great? It really is the best of both worlds. You get to be alive and unconscious.”

Comedian Rita Rudner, 1993

Now, by recording the brain waves and muscle movements of sleeping participants, and by observing and occasionally waking them, researchers are solving some of sleep’s deepest mysteries. Perhaps you can anticipate some of their discoveries. Are the following statements true or false?

When people dream of performing some activity, their limbs often move in concert with the dream.

Older adults sleep more than young adults.

Sleepwalkers are acting out their dreams.

Sleep experts recommend treating insomnia with an occasional sleeping pill.

Some people dream every night; others seldom dream.

All these statements (adapted from Palladino & Carducci, 1983) are *false*. To see why, read on.

Biological Rhythms and Sleep

Like the ocean, life has its rhythmic tides. Over varying time periods, our bodies fluctuate, and with them, our minds. Let's look more closely at two of those biological rhythms—our 24-hour biological clock and our 90-minute sleep cycle.

Circadian Rhythm

LOQ 3-5 How do our biological rhythms influence our daily functioning?

The rhythm of the day parallels the rhythm of life—from our waking at a new day's birth to our nightly return to what Shakespeare called “death's counterfeit.” Our bodies roughly synchronize with the 24-hour cycle of day and night thanks to an internal biological clock called the [circadian rhythm](#) (from the Latin *circa*, “about,” and *diem*, “day”). As morning nears, body temperature rises; it then peaks during the day, dips for a time in early afternoon (when many people take siestas or drink a caffeinated beverage), and begins to drop again in the evening. Thinking and memory improve as we approach our daily peak in circadian arousal. Try pulling an all-nighter or working an occasional night shift. You'll feel groggiest in the middle of the night but may gain new alertness when your normal wake-up time arrives.

circadian [ser-KAY-dee-an] **rhythm** our biological clock; regular bodily rhythms (for example, of temperature and wakefulness) that occur on a 24-hour cycle.

Eric Isselee/Shutterstock

Some students sleep like the fellow who stayed up all night to see where the Sun went. (Then it dawned on him.)

Age and experience can alter our circadian rhythm. Most 20-year-olds are evening-energized “owls,” with performance improving across the day (May & Hasher, 1998). Most older adults are morning-loving “larks,” with performance declining as the day wears on. By mid-evening, when the night has hardly begun for many young adults, retirement homes are typically quiet. After about age 20 (slightly earlier for women), we begin to shift from being owls to being larks (Roenneberg et al., 2004). Women become more morning oriented as they have children and also as they transition to menopause (Leonhard & Randler, 2009; Randler & Bausback, 2010). In general, night owls tend to be smart and creative (Giampietro & Cavallera, 2007). Morning types tend to do better in school, take more initiative, be more punctual, and be less vulnerable to depression (Preckel et al., 2013; Randler, 2008, 2009; Werner et al., 2015).

Sleep Stages

LOQ 3-6 What is the biological rhythm of our sleeping and dreaming stages?

Sooner or later, sleep overtakes us all, and consciousness fades as different parts of our brain’s cortex stop communicating (Massimini et al., 2005). Yet the sleeping brain remains active and has its own biological rhythm.

Peter Chadwick/Science Source

About every 90 minutes, we cycle through distinct sleep stages. This fact came to light when 8-year-old Armond Aserinsky went to bed one night in 1952. His father, Eugene, a University of Chicago graduate student, needed to test an electroencephalograph machine he had repaired that day (Aserinsky, 1988; Seligman & Yellen, 1987). Placing electrodes near Armond's eyes to record the rolling eye movements then believed to occur during sleep, Aserinsky watched the machine go wild, tracing deep zigzags on the graph paper. Could the machine still be broken? As the night proceeded and the activity recurred, Aserinsky realized that the periods of fast, jerky eye movements were accompanied by energetic brain activity. Awakened during one such episode, Armond reported having a dream. Aserinsky had discovered what we now know as **REM sleep** (rapid eye movement sleep).

REM sleep rapid eye movement sleep; a recurring sleep stage during which vivid dreams commonly occur. Also known as *paradoxical sleep*, because the muscles are relaxed (except for minor twitches) but other body systems are active.

Similar procedures used with thousands of volunteers showed the cycles were a normal part of sleep (Kleitman, 1960). To appreciate these studies, imagine yourself as a participant. As the hour grows late, you feel sleepy and yawn in response to reduced brain metabolism. (Yawning, which is also socially contagious, stretches your neck muscles and increases your heart rate, which increases your alertness [Moorcroft, 2003].) When you are ready for bed, a researcher comes in and tapes electrodes to your scalp (to detect your brain waves), on your chin (to detect muscle tension), and just outside

the corners of your eyes (to detect eye movement; [FIGURE 3.9](#)). Other devices will record your heart rate, respiration rate, and genital arousal.

FIGURE 3.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Hank Morgan/Science Source

FIGURE 3.9 Measuring sleep activity

Sleep researchers measure brain-wave activity, eye movements, and muscle tension with electrodes that pick up weak electrical signals from the brain, eyes, and facial muscles (Dement, 1978).

When you are in bed with your eyes closed, the researcher in the next room sees on the EEG the relatively slow [alpha waves](#) of your awake but relaxed state ([FIGURE 3.10](#)). As you adapt to all this equipment, you grow tired and, in an unremembered moment, slip into sleep ([FIGURE 3.11](#)). This transition is marked by the slowed breathing and the irregular brain waves of non-REM stage 1 sleep. Using the American Academy of Sleep Medicine classification of sleep stages, this is called *NREM-1* (Silber et al., 2007).

alpha waves the relatively slow brain waves of a relaxed, awake state.

FIGURE 3.10 Myers/DeWall, *Psychology*, 12e,

Rebecca Spencer, University of Massachusetts,
assisted with this illustration.

FIGURE 3.10 Brain waves and sleep stages

The beta waves of an alert, waking state and the regular alpha waves of an awake, relaxed state differ from the slower, larger delta waves of deep NREM-3 sleep. Although the rapid REM sleep waves resemble the near-waking NREM-1 sleep waves, the body is more internally aroused during REM sleep than during NREM (*non-REM*) sleep.

FIGURE 3.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.11 The moment of sleep

We seem unaware of the moment we fall into sleep, but someone watching our brain waves could tell (Dement, 1999).

Dolphins, porpoises, and whales sleep with one side of their brain at a time (Miller et al., 2008).

In one of his 15,000 research participants, William Dement (1999) observed the moment the brain's perceptual window to the outside world slammed shut. Dement asked a sleep-deprived young man with eyelids taped open to press a button every time a strobe light flashed in his eyes (about every 6 seconds). After a few minutes the young man missed one. Asked why, he said, "Because there was no flash." But there was a flash. He missed it because (as his brain activity revealed) he had fallen asleep for 2 seconds, missing not only the flash 6 inches from his nose but also the awareness of the abrupt moment of entry into sleep.

"My problem has always been an overabundance of alpha waves."

Sidney Harris/Science Cartoons Plus

During this brief NREM-1 sleep you may experience fantastic images resembling [hallucinations](#)—sensory experiences that occur without a sensory

stimulus. You may have a sensation of falling (at which moment your body may suddenly jerk) or of floating weightlessly. These *hypnagogic* sensations may later be incorporated into your memories. People who claim they were abducted by aliens—often shortly after getting into bed—commonly recall being floated off of or pinned down on their beds (Clancy, 2005; McNally, 2012).

hallucinations false sensory experiences, such as seeing something in the absence of an external visual stimulus.

You then relax more deeply and begin about 20 minutes of *NREM-2* sleep, with its periodic *sleep spindles*—bursts of rapid, rhythmic brain-wave activity. Although you could still be awakened without too much difficulty, you are now clearly asleep.

To catch your own hypnagogic experiences, you might use your alarm's snooze function.

Then you transition to the deep sleep of *NREM-3*. During this slow-wave sleep, which lasts for about 30 minutes, your brain emits large, slow **delta waves** and you are hard to awaken. (It is at the end of this stage that children may wet the bed.)

delta waves the large, slow brain waves associated with deep sleep.

 To better understand EEG readings and their relationship to consciousness, sleep, and dreams, experience the tutorial and simulation of **PsychSim 6: EEG and Sleep Stages**.

REM Sleep

About an hour after you first fall asleep, a strange thing happens. Rather than continuing in deep slumber, you ascend from your initial sleep dive. Returning through NREM-2 (where you'll ultimately spend about half your night), you enter the most intriguing of the four sleep phases—REM sleep ([FIGURE 3.12](#)). For about 10 minutes, your brain waves become rapid and saw-toothed, more like those of the nearly awake NREM-1 sleep. But unlike NREM-1, during REM sleep your heart rate rises, your breathing becomes rapid and irregular, and every half-minute or so your closed eyes dart around in momentary bursts of activity. These eye movements announce the beginning of a dream—often emotional, usually story-like, and richly hallucinatory. Dreams aren't real, but REM sleep tricks your brain into responding as if you are actually watching a real scene (Andrillon et al., 2015). Because anyone watching a sleeper's eyes can notice these REM bursts, it is amazing that science was ignorant of REM sleep until 1952.

FIGURE 3.12 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.12 The stages in a typical night's sleep

People pass through a multistage sleep cycle several times each night, with the periods of deep sleep diminishing and REM sleep periods increasing in duration. As people age, sleep becomes more fragile, with awakenings common among older adults (Kamel & Gammack, 2006; Neubauer, 1999).

Except during very scary dreams, your genitals become aroused during REM sleep. You have an erection or increased vaginal lubrication and clitoral engorgement, regardless of whether the dream's content is sexual (Karacan et al., 1966). Men's common "morning erection" stems from the night's last REM period, often just before waking. In young men, sleep-related erections outlast REM periods, lasting 30 to 45 minutes on average (Karacan et al., 1983; Schiavi & Schreiner-Engel, 1988). A typical 25-year-old man therefore has an erection during nearly half his night's sleep, a 65-year-old man for one-quarter. Many men troubled by occasional erectile difficulties get sleep-related erections, suggesting the problem is not between their legs.

During REM sleep, your brain's motor cortex is active, but your brainstem blocks its messages. This leaves your muscles relaxed, so much so that, except for an occasional finger, toe, or facial twitch, you are essentially paralyzed. Moreover, you cannot easily be awakened. (This immobility may occasionally linger as you awaken from REM sleep, producing a disturbing experience of *sleep paralysis* [Santomauro & French, 2009].) REM sleep is thus sometimes called *paradoxical sleep*: The body is internally aroused, with waking-like brain activity, yet asleep and externally calm.

The sleep cycle repeats itself about every 90 minutes for younger adults (with shorter, more frequent cycles for older adults). As the night goes on, deep NREM-3 sleep grows shorter and disappears, and REM and NREM-2 sleep periods get longer (see [Figure 3.12](#)). By morning, we have spent 20 to 25 percent of an average night's sleep—some 100 minutes—in REM sleep. In sleep lab studies, 37 percent of participants have reported rarely or never having dreams that they "can remember the next morning" (Moore, 2004). Yet even they, more than 80 percent of the time, could recall a dream after being awakened during REM sleep. We spend about 600 hours a year experiencing some 1500 dreams, or more than 100,000 dreams over a typical lifetime—dreams swallowed by the night but not acted out, thanks to REM's protective paralysis.

RP-4 Why would communal sleeping provide added protection for those whose safety depends upon vigilance, such as these soldiers (above)?

ANSWER: With each soldier cycling through the sleep stages independently, it is very likely that at any given time at least one will be in an easily awakened stage in the event of a threat.

RP-5 What are the four sleep stages, and in what order do we normally travel through those stages?

ANSWER: REM, NREM-1, NREM-2, NREM-3; normally we move through NREM-1, then NREM-2, then NREM-3, then back up through NREM-2 before we experience REM sleep.

RP-6 Can you match the cognitive experience with the sleep stage?

1. NREM-1
2. NREM-3
3. REM
 - a. story-like dream
 - b. fleeting images
 - c. minimal awareness

ANSWER: 1. b, 2. c, 3. a

Horses, which spend 92 percent of each day standing and can sleep standing, must lie down for REM sleep (Morrison, 2003).

What Affects Our Sleep Patterns?

LOQ 3-7 How do biology and environment interact in our sleep patterns?

True or false? “Everyone needs 8 hours of sleep.” *False*. Newborns often sleep two-thirds of their day, most adults no more than one-third (with some thriving on fewer than 6 hours nightly, others racking up 9 or more). There is more to our sleep differences than age. Some are awake between nightly sleep periods—sometimes called “first sleep” and “second sleep” (Randall, 2012). And some find that a 15-minute midday nap is as effective as another hour of nighttime sleep (Horne, 2011).

Sleep patterns are genetically influenced. Researchers are tracking the sleep-regulating genes in humans and other animals (Hayashi et al., 2015; Mackenzie et al., 2015). Sleep patterns are also culturally influenced. In Britain, Canada, Germany, Japan, and the United States, adults average 7 hours of sleep a night on workdays, and 7 to 8 hours on other days (NSF, 2013). The weeknight sleep of many students and workers falls short of this average, however (NSF, 2008). Earlier school start times, more extracurricular activities, and a lack of parent-set bedtime leads American adolescents to get less sleep than their Australian counterparts (Short et al., 2013). Thanks to modern lighting, shift work, and social media diversions, many who might have gone to bed at 9:00 p.m. a century ago are now up until 11:00 p.m. or later. With sleep, as with waking behavior, biology and environment interact.

Whether for work or play, bright light tweaks the circadian clock by activating light-sensitive retinal proteins. These proteins control the circadian clock by triggering signals to the brain’s [suprachiasmatic nucleus \(SCN\)](#)—a pair of grain-of-rice-sized, 10,000-cell clusters in the hypothalamus ([FIGURE 3.13](#)). The SCN does its job partly by causing the brain’s pineal gland to decrease its production of the sleep-inducing hormone *melatonin* in the morning and to increase it in the evening (Chang et al., 2015; Gandhi et al., 2015).

suprachiasmatic nucleus (SCN) a pair of cell clusters in the hypothalamus that controls circadian rhythm. In response to light, the SCN causes the pineal gland to adjust melatonin production, thus modifying our feelings of sleepiness.

FIGURE 3.13 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.13 The biological clock

Light striking the retina signals the suprachiasmatic nucleus (SCN) to suppress the pineal gland's production of the sleep hormone melatonin. At night, the SCN quiets down, allowing the pineal gland to release melatonin into the bloodstream.

People rarely snore during dreams. When REM starts, snoring stops.

Being bathed in (or deprived of) light disrupts our 24-hour biological clock (Czeisler et al., 1999; Dement, 1999). Night-shift workers may experience a chronic state of *desynchronization*. As a result, they become more likely to develop fatigue, stomach problems, heart disease, and, for women, breast cancer (Knutsson & Bøggild, 2010; Lin et al., 2015; Puttonen et al., 2009). Curiously—given that our ancestors' body clocks were attuned to the rising and setting Sun of the 24-hour day—many of today's young adults adopt something closer to a 25-hour day, by staying up too late to get 8 hours of sleep. For this, we can thank (or blame) Thomas Edison, inventor of the light bulb. Approximately 90 percent of Americans report using a light-emitting electronic device one hour before going to sleep (Chang et al., 2015). Such artificial light delays sleep.

Sleep often eludes those who stay up late and sleep in on weekends, and then go to bed earlier on Sunday evening in preparation for the new workweek (Oren & Terman, 1998). Like New Yorkers readjusting after a trip

to California, they experience “social jet lag.” For North Americans who fly to Europe and need to be up when their circadian rhythm cries “*SLEEP*,” bright light (spending the next day outdoors) helps reset the biological clock (Czeisler et al., 1986, 1989; Eastman et al., 1995).

RETRIEVAL PRACTICE

RP-7 The _____ nucleus helps monitor the brain’s release of melatonin, which affects our _____ rhythm.

ANSWER: suprachiasmatic, circadian

A circadian disadvantage: One study of more than 24,000 Major League Baseball games found that teams who had crossed three time zones before playing a series had nearly a 60 percent chance of losing their first game (Winter et al., 2009).

Why Do We Sleep?

LOQ 3-8 What are sleep’s functions?

So, our sleep patterns differ from person to person and from culture to culture. But why do we have this need for sleep? Psychologists offer five possible reasons:

Sleep protects. When darkness shut down the day’s hunting, gathering, and travel, our distant ancestors were better off asleep in a cave, out of harm’s way. Those who didn’t wander around dark cliffs were more likely to leave descendants. This fits a broader principle: A species’ sleep pattern tends to suit its ecological niche (Siegel, 2009). Animals with the greatest need to graze and the least ability to hide tend to sleep less. Animals also sleep less, with no ill effects, during times of mating and migration (Siegel, 2012). (For a sampling of animal sleep times, see [FIGURE 3.14](#).)

Sleep helps us recuperate. Sleep helps restore the immune system and repair brain tissue. Sleep gives resting neurons time to repair themselves, while pruning or weakening unused connections (Ding et al., 2016). Bats and other animals with high waking metabolism burn a lot of calories, producing *free radicals*, molecules that are toxic to neurons. Sleep sweeps away this toxic waste (Xie et al., 2013). Think of it this way: When consciousness leaves your house, workers come in to clean, saying “Good night. Sleep tidy.”

Sleep helps restore and rebuild our fading memories of the day’s experiences. To sleep is to strengthen. Sleep *consolidates* our memories by replaying recent learning and strengthening neural connections (Pace-Schott et al., 2015; Yang et al., 2014). It reactivates recent experiences stored in the hippocampus and shifts them for permanent storage elsewhere in the cortex (Racsmány et al., 2010; Urbain et al., 2016). Adults, children, and infants trained to perform tasks therefore recall them better after a night’s sleep, or even after a short nap, than after several hours awake (Friedrich et al., 2015; Seehagen et al., 2015). Older adults’ more frequently disrupted sleep also disrupts memory consolidation (Boyce et al., 2016; Pace-Schott & Spencer, 2011). After sleeping well, older people remember more of recently learned material (Drummond, 2010). Sleep, it seems, strengthens memories in a way

that being awake does not.

Sleep feeds creative thinking. Dreams can inspire noteworthy artistic and scientific achievements, such as the dreams that clued chemist August Kekulé to the structure of benzene (Ross, 2006) and inspired medical researcher Carl Alving (2011) to invent the vaccine patch. More commonplace is the boost that a complete night's sleep gives to our thinking and learning. After working on a task, then sleeping on it, people solve difficult problems more insightfully than do those who stay awake (Barrett, 2011; Sio et al., 2013). They also are better at spotting connections among novel pieces of information (Ellenbogen et al., 2007; Whitehurst et al., 2016). To think smart and see connections, it often pays to ponder a problem just before bed and then sleep on it.

Sleep supports growth. During slow-wave sleep, which occurs mostly in the first half of a night's sleep, the pituitary gland releases a growth hormone that is necessary for muscle development.

A regular full night's sleep can “*dramatically* improve your athletic ability,” report James Maas and Rebecca Robbins (2010). REM sleep and NREM-2 sleep—which occur mostly in the final hours of a long night's sleep—also help strengthen the neural connections that build enduring memories, including the “muscle memories” learned while practicing tennis or shooting baskets. Sleep promotes both a strong body and a strong mind. Well-rested athletes have faster reaction times, more energy, and greater endurance, and teams that build 8 to 10 hours of daily sleep into their training show improved performance. One study of Stanford University men's basketball players found that when their average sleep increased 110 minutes per night over the course of several weeks, their sprint times decreased, and their free throw and 3-point shooting percentages both increased 9 percent (Mah et al., 2011). Swimmer Conner Jaeger, who won a silver medal at the 2016 Olympics, takes sleep seriously. “Part of our training that we really just started to focus on,” he said, “is sleep” (Mayberry, 2016).

Maas, who has been a sleep consultant for college and professional athletes and teams, also advised basketball's Orlando Magic and figure skating's Sarah Hughes to cut their early-morning practices as part of a recommended sleep regimen. Soon thereafter, Hughes' performance scores increased, ultimately culminating in her 2002 Olympic gold medal. Given all the benefits of sleep, it's no wonder that sleep loss hits us so hard.

TIMOTHY A. CLARY/AFP/Getty Images

Ample sleep supports skill learning and high performance

This was the experience of Olympic gold medalist Sarah Hughes.

RETRIEVAL PRACTICE

RP-8 What are five proposed reasons for our need for sleep?

ANSWER: (1) Sleep has survival value. (2) Sleep helps us restore the immune system and repair brain tissue. (3) During sleep we consolidate memories. (4) Sleep fuels creativity. (5) Sleep plays a role in the growth process.

Sleep Deprivation and Sleep Disorders

LOQ 3-9 How does sleep loss affect us, and what are the major sleep disorders?

When our body yearns for sleep but does not get it, we begin to feel terrible. Trying to stay awake, we will eventually lose. In the tiredness battle, sleep always wins.

Effects of Sleep Loss

Today, more than ever, our sleep patterns leave us not only sleepy but drained of energy and feelings of well-being. This tiredness tendency has grown so steadily that some researchers have labeled current times the “Great Sleep Recession” (Keyes et al., 2015). After a succession of 5-hour nights, we accumulate a sleep debt that cannot be satisfied by one long sleep. “The brain keeps an accurate count of sleep debt for at least two weeks,” reported sleep researcher William Dement (1999, [p. 64](#)).

Obviously, then, we need sleep. Sleep commands roughly one-third of our lives—some 25 years, on average. Allowed to sleep unhindered, most adults will sleep at least 9 hours a night (Coren, 1996). With that much sleep, we awaken refreshed, sustain better moods, and perform more efficiently and accurately. The U.S. Navy and the National Institutes of Health have demonstrated the benefits of unrestricted sleep in experiments in which volunteers spent 14 hours daily in bed for at least a week. For the first few days, the volunteers averaged 12 hours of sleep or more per day, apparently paying off a sleep debt that averaged 25 to 30 hours. That accomplished, they then settled back to 7.5 to 9 hours nightly and felt energized and happier (Dement, 1999). In one Gallup survey (Mason, 2005), 63 percent of adults who reported getting the sleep they needed also reported being “very satisfied” with their personal life (as did only 36 percent of those needing more sleep). And when 909 working women reported on their daily moods, the researchers were struck by what mattered little (such as money, so long as the person was not battling poverty), and what mattered a lot: less time pressure at work and a good night’s sleep (Kahneman et al., 2004).

In 1989, Michael Doucette was named America's Safest Driving Teen. In 1990, while driving home from college, he fell asleep at the wheel and collided with an oncoming car, killing both himself and the other driver. Michael's driving instructor later acknowledged never having mentioned sleep deprivation and drowsy driving (Dement, 1999).

College and university students are especially sleep deprived; 69 percent in one national survey reported "feeling tired" or "having little energy" on at least several days during the two previous weeks (AP, 2009). For students, less sleep also predicts more conflicts in friendships and romantic relationships (Gordon & Chen, 2014; Tavernier & Willoughby, 2014). Tiredness triggers testiness. In another survey, 28 percent of high school students acknowledged falling asleep in class at least once a week (NSF, 2006). The going needn't get boring before students start snoring.

In a 2013 Gallup poll, 40 percent of Americans reported getting 6 hours or less sleep a night (Jones, 2013).

To see whether you are one of the many sleep-deprived students, engage online with the self-assessment activity **Assess Your Strengths: Sleep Deprivation**.

Sleep loss is also a predictor of depression (Baglioni et al., 2016). Researchers who studied 15,500 12- to 18-year-olds found that those who slept 5 or fewer hours a night had a 71 percent higher risk of depression than their peers who slept 8 hours or more (Gangwisch et al., 2010). This link does not appear to reflect an effect of depression on sleep. When children and youth are followed through time, sleep loss predicts depression rather than vice versa (Gregory et al., 2009). Moreover, REM sleep's processing of emotional experiences helps protect against depression (Walker & van der Helm, 2009). After a good night's sleep, we often do feel better the next day. And that may help to explain why parentally enforced bedtimes predict less depression, and why pushing back school start times leads to improved adolescent sleep, alertness, and mood (Perkinson-Gloor et al., 2013; Winsler et al., 2015). Thus, European high schools rarely start before 9 a.m. (Fischetti,

2014). And the American Academy of Pediatrics (2014) advocates similarly delaying adolescents' school start times to "allow students the opportunity to achieve optimal levels of sleep (8.5–9.5 hours)."

"Maybe 'Bring Your Pillow To Work Day' wasn't such a good idea."

© 2011 Marty Bucella

"You wake up in the middle of the night and grab your smartphone to check the time—it's 3 a.m.—and see an alert. Before you know it, you fall down a rabbit hole of email and Twitter. Sleep? Forget it."

Nick Bilton, "Disruptions: For a Restful Night, Make Your Smartphone Sleep on the Couch," 2014

Sleep-deprived students often function below their peak. And they know it: Four in five teens and three in five 18- to 29-year-olds wish they could get more sleep on weekdays (Mason, 2003, 2005). "Sleep deprivation has consequences—difficulty studying, diminished productivity, tendency to make mistakes, irritability, fatigue," noted Dement (1999, [p. 231](#)). A large sleep debt "makes you stupid." Yet that teen who staggers glumly out of bed in response to an unwelcome alarm, yawns through morning classes, and feels half-depressed much of the day may be energized at 11:00 p.m. and unmindful of the next day's looming sleepiness (Carskadon, 2002).

Lack of sleep can also make you gain weight. Sleep deprivation

- increases *ghrelin*, a hunger-arousing hormone, and decreases its hunger-suppressing partner, *leptin* (Shilsky et al., 2012).
- decreases metabolic rate, a gauge of energy use (Buxton et al., 2012).
- increases production of *cortisol*, a stress hormone that stimulates the body to make fat.

“Remember to sleep because you have to sleep to remember.”

James B. Maas and Rebecca S. Robbins, *Sleep for Success*, 2010

- enhances limbic brain responses to the mere sight of food and decreases cortical responses that help us resist temptation (Benedict et al., 2012; Greer et al., 2013; St-Onge et al., 2012).

Thus, children and adults who sleep less are heavier than average, and in recent decades people have been sleeping less and weighing more (Shiromani et al., 2012; Suglia et al., 2014). Moreover, experimental sleep deprivation increases appetite and eating; our tired brain finds fatty foods more enticing (Fang et al., 2015; Hanlon et al., 2015). So, sleep loss helps explain the weight gain common among sleep-deprived students (Hull et al., 2007).

Sleep also affects our physical health. When infections do set in, we typically sleep more, boosting our immune cells. Sleep deprivation can suppress immune cells that battle viral infections and cancer (Möller-Levet et al., 2013; Motivala & Irwin, 2007; Opp & Krueger, 2015). One experiment exposed volunteers to a cold virus. Those who averaged less than 5 hours' sleep a night were 4.5 times more likely to develop a cold than those who slept more than 7 hours a night (Prather et al., 2015). Sleep's protective effect may help explain why people who sleep 7 to 8 hours a night tend to outlive those who are chronically sleep deprived, and why older adults who have no difficulty falling or staying asleep tend to live longer than their sleep-deprived agemates (Dew et al., 2003; Parthasarathy et al., 2015; Scullin & Bliwise, 2015).

Sleep deprivation slows reactions and increases errors on visual attention tasks similar to those involved in screening airport baggage, performing surgery, and reading X-rays (Caldwell, 2012; Lim & Dinges, 2010). Slow responses can also spell disaster for those operating equipment, piloting, or

driving. Drowsy driving has contributed to an estimated one in six American traffic accidents (AAA, 2010) and to some 30 percent of Australian highway deaths (Maas, 1999). One two-year study examined the driving accidents of more than 20,000 Virginia 16- to 18-year-olds in two major cities. In one city, the high schools started 75 to 80 minutes later than in the other. The late starters had about 25 percent fewer crashes (Vorona et al., 2011). When sleepy frontal lobes confront an unexpected situation, misfortune often results.

Stanley Coren capitalized on what is, for many North Americans, a semi-annual sleep-manipulation experiment—the “spring forward” to daylight saving time and “fall back” to standard time. Searching millions of Canadian and U.S. records, Coren found that accidents increased immediately after the spring-forward time change, which shortens sleep ([FIGURE 3.15](#)).

FIGURE 3.15 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.15 Less sleep = more accidents

On the Monday after the spring time change, when people lose one hour of sleep, accidents increased, as compared with the Monday before. In the fall, traffic accidents normally increase because of greater snow, ice, and darkness, but they diminished after the time change. (Data from Coren, 1996.)

“So shut your eyes
Kiss me goodbye
And sleep
Just sleep.”

My Chemical Romance, “Sleep”

The same spring-forward effect appeared in another study, which showed that tired people are more likely to “cyberloaf”—to fritter away time online. On the Monday after daylight saving time begins, entertainment-related Google searches have been 3.1 percent higher than on the preceding Monday, and 6.4 percent higher than on the following Monday (Wagner et al., 2012a).

FIGURE 3.16 summarizes the effects of sleep deprivation. But there is good news! Psychologists have discovered a treatment that strengthens memory, increases concentration, boosts mood, moderates hunger, reduces obesity, fortifies the immune system, and lessens the risk of fatal accidents. Even better news: The treatment feels good, it can be self-administered, the supplies are limitless, and it’s free! If you are a typical university-age student, often going to bed near 2:00 a.m. and dragged out of bed six hours later by the dreaded alarm, the treatment is simple. Each night, just add 15 minutes to your sleep until you feel more like a rested and energized student and less like a zombie. For some additional tips on getting better quality sleep, see **TABLE 3.1**.

FIGURE 3.16 How sleep deprivation affects us

TABLE 3.1

Some Natural Sleep Aids

• Exercise regularly but not in the late evening. (Late afternoon is best.)
• Avoid caffeine after early afternoon, and avoid food and drink near bedtime. The exception would be a glass of milk, which provides raw materials for the manufacture of serotonin, a neurotransmitter that facilitates sleep.
• Relax before bedtime, using dimmer light.
• Sleep on a regular schedule (rise at the same time even after a restless night) and avoid long naps.
• Hide time displays so you aren't tempted to check repeatedly.
• Reassure yourself that temporary sleep loss causes no great harm.
• Focus your mind on nonarousing, engaging thoughts, such as song lyrics or vacation travel (Gellis et al., 2013).
• If all else fails, settle for less sleep, either going to bed later or getting up earlier.

Major Sleep Disorders

Do you have trouble sleeping when anxious or excited? Most of us do. An occasional loss of sleep is nothing to worry about. But for those who have a major sleep disorder—[insomnia](#), [narcolepsy](#), [sleep apnea](#), sleepwalking, sleepwalking, or [night terrors](#)—trying to sleep can be a nightmare. (See [TABLE 3.2](#) for a summary of these disorders.)

--

insomnia recurring problems in falling or staying asleep.

narcolepsy a sleep disorder characterized by uncontrollable sleep attacks. The sufferer may lapse directly into REM sleep, often at inopportune times.

sleep apnea a sleep disorder characterized by temporary cessations of breathing during sleep and repeated momentary awakenings.

night terrors a sleep disorder characterized by high arousal and an appearance of being terrified; unlike nightmares, night terrors occur during NREM-3 sleep, within two or three hours of falling asleep, and are seldom remembered.

TABLE 3.2
Sleep Disorders

Disorder	Rate	Description	Effects
<i>Insomnia</i>	1 in 10 adults; 1 in 4 older adults	Ongoing difficulty falling or staying asleep.	Chronic tiredness. Reliance on sleeping pills and alcohol, which reduce REM sleep and lead to tolerance—a state in which increasing doses are needed to produce an effect.
<i>Narcolepsy</i>	1 in 2000 adults	Sudden attacks of overwhelming sleepiness.	Risk of falling asleep at a dangerous moment. Narcolepsy attacks usually last less than 5 minutes, but they can happen at the worst and most emotional times. Everyday activities, such as driving, require extra caution.

<i>Sleep apnea</i>	1 in 20 adults	Stopping breathing repeatedly while sleeping.	Fatigue and depression (as a result of slow-wave sleep deprivation). Associated with obesity (especially among men).
<i>Sleepwalking and sleepwalking</i>	1–15 in 100 in the general population for sleepwalking (NSF, 2016b); about half of young children for sleepwalking (Reimão & Lefèvre, 1980)	Doing normal waking activities (sitting up, walking, speaking) while asleep. Sleepwalking can occur during any sleep stage. Sleepwalking happens in NREM-3 sleep.	Few serious concerns. Sleepwalkers return to their beds on their own or with the help of a family member, rarely remembering their trip the next morning.
<i>Night terrors</i>	1 in 100 adults; 1 in 30 children	Appearing terrified, talking nonsense, sitting up, or walking around during NREM-3 sleep; different from nightmares.	Doubling of a child's heart and breathing rates during the attack. Luckily, children remember little or nothing of the fearful event the next day. As people age, night terrors become more and more rare.

Consider how researchers have addressed these issues by engaging online with **Immersive Learning: How Would You Know If Sleep Deprivation Affects Academic Performance?**

About 1 in 10 adults, and 1 in 4 older adults, complain of insomnia—persistent problems in either falling or staying asleep (Irwin et al., 2006). The result is tiredness and increased risk of depression (Baglioni et al., 2016).

From middle age on, awakening occasionally during the night becomes the norm, not something to fret over or treat with medication (Vitiello, 2009). Ironically, insomnia becomes worse when we fret about it. In laboratory studies, people with insomnia do sleep less than others. But they typically overestimate how long it takes them to fall asleep and underestimate how long they actually have slept (Harvey & Tang, 2012). Even if we have been awake only an hour or two, we may *think* we have had very little sleep because it's the waking part we remember.

The most common quick fixes for true insomnia—sleeping pills and alcohol—can aggravate the problem, reducing REM sleep and leaving the person with next-day blahs. Such aids can also lead to *tolerance*—a state in which increasing doses are needed to produce an effect.

“Sleep is like love or happiness. If you pursue it too ardently it will elude you.”

Wilse Webb, *Sleep: The Gentle Tyrant*, 1992

ANSWER: quick reaction times; gain weight

Dreams

LOQ 3-10 What do we dream, and what functions have theorists proposed for dreams?

Now playing at an inner theater near you: the premiere of a sleeping person's vivid dream. This never-before-seen mental movie features captivating

characters wrapped in a plot so original and unlikely, yet so intricate and so seemingly real, that the viewer later marvels at its creation.

Unlike daydreams, REM [dreams](#) are vivid, emotional, and often bizarre (Loftus & Ketcham, 1994). Waking from one, we may wonder how our brain can so creatively, colorfully, and completely construct this alternative world. In the shadowland between our dreaming and waking consciousness, we may even wonder for a moment which is real. Awakening from a nightmare, a 4-year-old may be sure there is a bear in the house.

dream a sequence of images, emotions, and thoughts passing through a sleeping person's mind.

Photofest/Warner Bros. Pictures

A dreamy take on dreamland

The 2010 movie *Inception* creatively played off our interest in finding meaning in our dreams, and in understanding the layers of our consciousness. It further explored the idea of creating false memories through the power of suggestion—an idea we will discuss in [Chapter 8](#).

“I do not believe that I am now dreaming, but I cannot prove that I am not.”

Philosopher Bertrand Russell (1872–1970)

Discovering the link between REM sleep and dreaming began a new era in dream research. Instead of relying on someone's hazy recall hours after having a dream, researchers could catch dreams as they happened. They could awaken people during or within 3 minutes after a REM sleep period and hear a vivid account.

What We Dream

We spend six years of our life in dreams, many of which are anything but sweet. For both women and men, 8 in 10 dreams are marked by at least one negative event or emotion (Domhoff, 2007). Common themes include repeatedly failing in an attempt to do something; being attacked, pursued, or rejected; or experiencing misfortune (Hall et al., 1982). Dreams with sexual imagery occur less often than you might think. In one study, only 1 in 10 dreams among young men and 1 in 30 among young women had sexual content (Domhoff, 1996).

More commonly, a dream's story line incorporates traces of previous days' nonsexual experiences and preoccupations (De Koninck, 2000):

- After suffering a trauma, people commonly report nightmares, which help extinguish daytime fears (Levin & Nielsen, 2007, 2009). One sample of Americans recording their dreams during September, 2001 reported an increase in threatening dreams following the 9/11 terrorist attacks (Propper et al., 2007). Compared with Palestinian children living in a peaceful town in Galilee, those living in the conflict-ridden Gaza Strip more often dream of aggression (Punamäki & Joustie, 1998).

“For what one has dwelt on by day, these things are seen in visions of the night.”

Menander of Athens (342–292 b.c.e.), *Fragments*

- Compared with nonmusicians, musicians report twice as many dreams of music (Uga et al., 2006).
- Studies in four countries have found blind people mostly dreaming of using their nonvisual senses (Buquet, 1988; Taha, 1972; Vekassy, 1977). But even natively blind people sometimes “see” in their dreams (Bértolo,

2005). Likewise, people born paralyzed below the waist sometimes dream of walking, standing, running, or cycling (Saurat et al., 2011; Voss et al., 2011).

Our two-track mind continues to monitor our environment while we sleep. Sensory stimuli—a particular odor or a phone’s ringing—may be instantly and ingeniously woven into the dream story. In a classic experiment, researchers lightly sprayed cold water on dreamers’ faces (Dement & Wolpert, 1958). Compared with sleepers who did not get the cold-water treatment, these people were more likely to dream about a waterfall, a leaky roof, or even about being sprayed by someone.

So, could we learn a foreign language by hearing it played while we sleep? If only. While sleeping we can learn to associate a sound with a mild electric shock (and to react to the sound accordingly). We can also learn to associate a particular sound with a pleasant or unpleasant odor (Arzi et al., 2012). But we do not remember recorded information played while we are soundly asleep (Eich, 1990; Wyatt & Bootzin, 1994). In fact, anything that happens during the 5 minutes just before we fall asleep is typically lost from memory (Roth et al., 1988). This explains why sleep apnea patients, who repeatedly awaken with a gasp and then immediately fall back to sleep, do not recall the episodes. Ditto someone who awakens momentarily, sends a text message, and the next day can’t remember doing so. It also explains why dreams that momentarily awaken us are mostly forgotten by morning. To remember a dream, get up and stay awake for a few minutes.

A popular sleep myth: If you dream you are falling and hit the ground (or if you dream of dying), you die. Unfortunately, those who could confirm these ideas are not around to do so. Many people, however, have had such dreams and are alive to report them.

“Follow your dreams, except for that one where you’re naked at work.”

Attributed to comedian Henny Youngman

Why We Dream

Dream theorists have proposed several explanations of why we dream, including these:

To satisfy our own wishes. In 1900, in his landmark book *The Interpretation of Dreams*, Sigmund Freud offered what he thought was “the most valuable of all the discoveries it has been my good fortune to make.” He proposed that dreams provide a psychic safety valve that discharges otherwise unacceptable feelings. He viewed a dream’s [manifest content](#) (the apparent and remembered story line) as a censored, symbolic version of its [latent content](#), the unconscious drives and wishes (often erotic) that would be threatening if expressed directly. Thus, a gun might be a disguised representation of a penis.

manifest content according to Freud, the remembered story line of a dream (as distinct from its latent, or hidden, content).

latent content according to Freud, the underlying meaning of a dream (as distinct from its manifest content).

“When people interpret [a dream] as if it were meaningful and then sell those interpretations, it’s quackery.”

Sleep researcher J. Allan Hobson (1995)

Freud considered dreams the key to understanding our inner conflicts. However, his critics say it is time to wake up from Freud’s dream theory, which they regard as a scientific nightmare. “There is no reason to believe any of Freud’s specific claims about dreams and their purposes,” observed dream researcher William Domhoff (2003). Some contend that even if dreams are symbolic, they could be interpreted any way one wished. Others maintain that dreams hide nothing: A dream about a gun is a dream about a gun. Legend has it that even Freud, who loved to smoke cigars, acknowledged that “sometimes, a cigar is just a cigar.” Freud’s wish-fulfillment theory of dreams has in large part given way to other theories.

To file away memories. The *information-processing* perspective proposes that dreams may help sift, sort, and fix the day's experiences in our memory. Some studies support this view. When tested the day after learning a task, those who had been deprived of both slow-wave and REM sleep did not do as well as those who had slept undisturbed (Stickgold, 2012). Other studies showed similar memory lapses for new material among people who were awakened every time they began REM sleep (Empson & Clarke, 1970; Karni & Sagi, 1994).

Brain scans confirm the link between REM sleep and memory. The brain regions that were active as rats learned to navigate a maze, or as people learned to perform a visual-discrimination task, became active again later during REM sleep (Louie & Wilson, 2001; Maquet, 2001). So precise were these activity patterns that scientists could tell where in the maze the rat would be if awake. To sleep, perchance to remember.

This is important news for students, many of whom, observed researcher Robert Stickgold (2000), suffer from a kind of sleep bulimia—sleep deprived on weekdays and binge sleeping on the weekend. “If you don’t get good sleep and enough sleep after you learn new stuff, you won’t integrate it effectively into your memories,” he warned. That helps explain why high school students with high grades slept about 25 minutes longer each night than their lower-achieving classmates (Wolfson & Carskadon, 1998; see [FIGURE 3.17](#)). Sacrificing sleep time to study actually *worsens* academic performance, by making it harder the next day to understand class material or do well on a test (Gillen-O’Neel et al., 2013).

FIGURE 3.17 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.17 A sleeping brain is a working brain

To develop and preserve neural pathways. Perhaps dreams, or the brain activity associated with REM sleep, serve a *physiological* function, providing

the sleeping brain with periodic stimulation. This theory makes developmental sense. Stimulating experiences preserve and expand the brain's neural pathways. Infants, whose neural networks are fast developing, spend much of their abundant sleep time in REM sleep ([FIGURE 3.18](#)).

FIGURE 3.18 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
swissmacky/Shutterstock

FIGURE 3.18 Sleep across the life span

As we age, our sleep patterns change. During our first few months, we spend progressively less time in REM sleep. During our first 20 years, we spend progressively less time asleep. (Data from Snyder & Scott, 1972.)

To make sense of neural static. Other theories propose that dreams erupt from neural activation spreading upward from the brainstem (Antrobus, 1991; Hobson, 2003, 2004, 2009). According to *activation-synthesis theory*, dreams are the brain's attempt to synthesize random neural activity. Much as a neurosurgeon can produce hallucinations by stimulating different parts of a patient's cortex, so can stimulation originating within the brain. As Freud might have expected, PET scans of sleeping people also reveal increased activity in the emotion-related limbic system (in the amygdala) during emotional dreams (Schwartz, 2012). In contrast, frontal lobe regions responsible for inhibition and logical thinking seem to idle, which may explain why our dreams are less inhibited than we are when awake (Maquet et al., 1996). Add the limbic system's emotional tone to the brain's visual bursts and—Voila!—we dream. Damage either the limbic system or the visual centers active during dreaming, and dreaming itself may be impaired (Domhoff, 2003).

Rapid eye movements also stir the liquid behind the cornea; this delivers fresh oxygen to corneal cells, preventing their suffocation.

Question: Does eating spicy foods cause us to dream more?

Answer: Any food that causes you to awaken more increases your chance of recalling a dream (Moorcroft, 2003).

To reflect cognitive development. Some dream researchers prefer to see dreams as part of brain maturation and cognitive development (Domhoff, 2010, 2011; Foulkes, 1999). For example, prior to age 9, children’s dreams seem more like a slide show and less like an active story in which the dreamer is an actor. Dreams overlap with waking cognition and feature coherent speech. They *simulate reality* by drawing on our concepts and knowledge. They engage brain networks that also are active during daydreaming—and so may be viewed as intensified mind wandering, enhanced by visual imagery (Fox et al., 2013). Unlike the idea that dreams arise from bottom-up brain activation, the cognitive perspective emphasizes our mind’s top-down control of our dream content (Nir & Tononi, 2010). Dreams, says G. William Domhoff (2014), “dramatize our wishes, fears, concerns, and interests in striking scenarios that we experience as real events.”

TABLE 3.3 compares these major dream theories. Although today’s sleep researchers debate dreams’ function—and some are skeptical that dreams serve any function—there is one thing they agree on: We need REM sleep. Deprived of it by repeated awakenings, people return more and more quickly to the REM stage after falling back to sleep. When finally allowed to sleep undisturbed, they literally sleep like babies—with increased REM sleep, a phenomenon called **REM rebound**. Most other mammals also experience REM rebound, suggesting that the causes and functions of REM sleep are deeply biological. (That REM sleep occurs in mammals—and not in animals such as fish, whose behavior is less influenced by learning—fits the information-processing theory of dreams.)

TABLE 3.3
Dream Theories

Theory	Explanation	Critical Considerations
--------	-------------	-------------------------

<i>Freud's wish-fulfillment</i>	Dreams provide a “psychic safety valve”—expressing otherwise unacceptable feelings; contain manifest (remembered) content and a deeper layer of latent content (a hidden meaning).	Lacks any scientific support; dreams may be interpreted in many different ways.
<i>Information-processing</i>	Dreams help us sort out the day's events and consolidate our memories.	But why do we sometimes dream about things we have not experienced and about past events?
<i>Physiological function</i>	Regular brain stimulation from REM sleep may help develop and preserve neural pathways.	This does not explain why we experience <i>meaningful</i> dreams.
<i>Activation-synthesis</i>	REM sleep triggers neural activity that evokes random visual memories, which our sleeping brain weaves into stories.	The individual's brain is weaving the stories, which still tells us something about the dreamer.
<i>Cognitive development</i>	Dream content reflects dreamers' level of cognitive development—their knowledge and understanding. Dreams simulate our lives, including worst-case scenarios.	Does not propose an adaptive function of dreams.

REM rebound the tendency for REM sleep to increase following REM sleep deprivation.

So does this mean that because dreams serve physiological functions and

extend normal cognition, they are psychologically meaningless? Not necessarily. Every psychologically meaningful experience involves an active brain. We are once again reminded of a basic principle: *Biological and psychological explanations of behavior are partners, not competitors.*

Dreams are a fascinating altered state of consciousness. But they are not the only altered states. As we will see next, drugs also alter conscious awareness.

RETRIEVAL PRACTICE

RP-10 What five theories propose explanations for why we dream?

ANSWER: (1) Freud's wish-fulfillment (dreams as a psychic safety valve), (2) information-processing (dreams sort the day's events and consolidate memories), (3) physiological function (dreams pave neural pathways), (4) activation-synthesis (REM sleep triggers random neural activity that the mind weaves into stories), and (5) cognitive development (dreams reflect the dreamer's developmental stage)

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only

help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Our body temperature tends to rise and fall in sync with a biological clock, which is referred to as _____.

During the NREM-1 sleep stage, a person is most likely to experience

- a. sleep spindles.
- b. hallucinations.
- c. night terrors or nightmares.
- d. rapid eye movements.

The brain emits large, slow delta waves during _____ sleep.

As the night progresses, what happens to the REM stage of sleep?

Which of the following is NOT one of the reasons that have been proposed to explain why we need sleep?

- a. Sleep has survival value.
- b. Sleep helps us recuperate.
- c. Sleep rests the eyes.
- d. Sleep plays a role in the growth process.

What is the difference between narcolepsy and sleep apnea?

In interpreting dreams, Freud was most interested in their

- a. information-processing function.
- b. physiological function.
- c. manifest content, or story line.
- d. latent content, or hidden meaning.

How has activation-synthesis been used to explain why we dream?

“For what one has dwelt on by day, these things are seen in visions of the night” (Menander of Athens, Fragments). How might we use the information-processing perspective on dreaming to interpret this ancient Greek quote?

The tendency for REM sleep to increase following REM sleep deprivation is referred to as _____.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Drugs and Consciousness

Tolerance and Addiction in Substance Use Disorders

LOQ 3-11 What are *substance use disorders*?

Let's imagine a day in the life of a legal drug user. It begins with a wake-up latte. By midday, several cigarettes have calmed frazzled nerves before an appointment at the plastic surgeon's office for wrinkle-smoothing Botox injections. An afternoon energy drink provides a needed boost. A diet pill before dinner helps curb the appetite. Later, a beer and two Advil PMs help offset those stimulating effects. And if performance needs enhancing, there are beta blockers for onstage performers, Viagra for middle-aged and older men, and Adderall for students hoping to focus their concentration.

Such substances are **psychoactive drugs**, chemicals that change perceptions and moods. Most of us manage to use some psychoactive drugs in moderation and without disrupting our lives. But sometimes, drug use crosses the line between moderation and **substance use disorder** ([TABLE 3.4](#)). A drug's overall effect depends not only on its biological effects but also on the user's expectations, which vary with social and cultural contexts (Gu et al., 2015; Ward, 1994). If one culture assumes that a particular drug produces euphoria (or aggression or sexual arousal) and another does not, each culture may find its expectations fulfilled. We'll take a closer look at these interacting forces in the use and potential abuse of particular psychoactive drugs. But first, let's consider what contributes to the disordered use of various substances. (See Thinking Critically About: Tolerance and Addiction.)

psychoactive drug a chemical substance that alters perceptions and moods.

substance use disorder a disorder characterized by continued substance craving and use despite significant life disruption and/or physical risk.

TABLE 3.4

When Is Drug Use a Disorder?

According to the American Psychiatric Association, a person may be diagnosed with *substance use disorder* when drug use continues despite significant life disruption. Resulting brain changes may persist after quitting use of the substance (thus leading to strong cravings when exposed to people and situations that trigger memories of drug use). The severity of substance use disorder varies from *mild* (two to three of the indicators listed below) to *moderate* (four to five indicators) to *severe* (six or more indicators). (Source: American Psychiatric Association, 2013.)

Diminished Control
1. Uses more substance, or for longer, than intended.
2. Tries unsuccessfully to regulate use of substance.
3. Spends much time acquiring, using, or recovering from effects of substance.
4. Craves the substance.
Diminished Social Functioning
5. Use disrupts commitments at work, school, or home.
6. Continues use despite social problems.
7. Causes reduced social, recreational, and work activities.
Hazardous Use
8. Continues use despite hazards.
9. Continues use despite worsening physical or psychological problems.
Drug Action
10. Experiences tolerance (needing more substance for the desired effect).
11. Experiences withdrawal when attempting to end use.

Thinking Critically About:

Tolerance and Addiction

LOQ 3-12 What roles do tolerance and addiction play in substance use disorders, and how has the concept of addiction changed?

Tolerance

With continued use of alcohol and some other drugs (but not marijuana), users develop **tolerance** as their brain chemistry adapts to offset the drug effect (*neuroadaptation*). To experience the same effect, users require larger and larger doses, which increase the risk of becoming *addicted* and developing a *substance use disorder*.

Drinks rarely

Drinks frequently

Addiction

Caused by ever-increasing doses of most psychoactive drugs (including prescription painkillers). Prompts user to crave the drug, to continue use despite adverse consequences, and to struggle when attempting to **withdraw** from it. These behaviors suggest a *substance use disorder*. Once in the grip of addiction, people *want* the drug more than they *like* the drug.¹

4% of the world's people have an alcohol use disorder.²

The lifetime odds of getting hooked after using various drugs:

9%	Marijuana
21%	Cocaine
23%	Alcohol
68%	Tobacco

Source: National Epidemiologic Survey on Alcohol and Related Conditions³

Therapy or group support, such as from Alcoholics Anonymous, may help. It also helps to believe that addictions are controllable and that people can change. Many people do voluntarily stop using addictive drugs, without any treatment. Most ex-smokers have kicked the habit on their own.⁴

Behavior Addictions

Psychologists try to avoid using "addiction" to label driven, excessive behaviors such as eating, work, sex, and accumulating wealth.

I'm ADDICTED to cheeseburgers!

Yet some behaviors can become compulsive and dysfunctional—similar to problematic alcohol and drug use.⁵

- Behavior addictions include *gambling disorder*.
- *Internet gaming disorder* has been proposed "for further study."⁶ Some Internet users display an apparent inability to resist logging on and staying on, even when this excessive use impairs their work and relationships.⁷

Psychological and drug therapies may be "highly effective" for problematic Internet use.⁸

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

RETRIEVAL PRACTICE

RP-11 What is the process that leads to drug tolerance?

ANSWER: With repeated exposure to a psychoactive drug, the user's brain chemistry adapts and the drug's effect lessens. Thus, it takes bigger doses to get the desired effect.

Types of Psychoactive Drugs

The three major categories of psychoactive drugs are *depressants*, *stimulants*, and *hallucinogens*. All do their work at the brain's synapses, stimulating, inhibiting, or mimicking the activity of the brain's own chemical messengers, the neurotransmitters.

Depressants

LOQ 3-13 What are *depressants*, and what are their effects?

Depressants are drugs such as alcohol, barbiturates (tranquilizers), and opiates that calm neural activity and slow body functions.

depressants drugs (such as alcohol, barbiturates, and opiates) that reduce neural activity and slow body functions.

ALCOHOL True or false? Alcohol is a depressant in large amounts but is a stimulant in small amounts. *False*. In any amount, alcohol is a depressant. Low doses of alcohol may, indeed, enliven a drinker, but they do so by acting as a *disinhibitor*—they slow brain activity that controls judgment and inhibitions. Alcohol is an equal-opportunity drug: It increases (disinhibits) helpful tendencies—as when tipsy restaurant patrons leave extravagant tips and social drinkers bond in groups (Fairbairn & Sayette, 2014; Lynn, 1988). And it increases harmful tendencies, as when sexually aroused men become more disposed to sexual aggression. One University of Illinois campus survey showed that before sexual assaults, 80 percent of the male assailants and 70 percent of the female victims had been drinking (Camper, 1990). Another survey of 89,874 American collegians found alcohol or drugs involved in 79 percent of unwanted sexual intercourse experiences (Presley et al., 1997). When drinking, both men and women are more disposed to casual sex (Claxton et al., 2015; Johnson & Chen, 2015). *The bottom line*: The urges you would feel if sober are the ones you will more likely act upon when intoxicated.

The prolonged and excessive drinking that characterizes **alcohol use disorder** can shrink the brain (**FIGURE 3.19**). Women, who have less of a stomach enzyme that digests alcohol, are especially vulnerable (Wuethrich, 2001). Girls and young women can become addicted to alcohol more quickly than boys and young men do, and they are at risk for lung, brain, and liver damage at lower consumption levels (CASA, 2003).

alcohol use disorder (popularly known as *alcoholism*) alcohol use marked by

tolerance, withdrawal, and a drive to continue problematic use.

FIGURE 3.19 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Daniel Hommer, NIAAA, NIH, HHS

FIGURE 3.19 Disordered drinking shrinks the brain

MRI scans show brain shrinkage in women with alcohol use disorder (left) compared with women in a control group (right).

Slowed Neural Processing Alcohol slows sympathetic nervous system activity. In low doses, it relaxes the drinker. In larger doses, it causes reactions to slow, speech to slur, and skilled performance to deteriorate. Paired with sleep deprivation, alcohol is a potent sedative. Add these physical effects to lowered inhibitions, and the result can be deadly. Worldwide, several hundred thousand lives are lost each year in alcohol-related accidents and violent crime. As blood-alcohol levels rise and judgment falters, people's qualms about drinking and driving lessen. In experiments, virtually all drinkers who had insisted when sober that they would not drive under the influence later decided to drive home from a bar, even if given a Breathalyzer test and told they were intoxicated (Denton & Krebs, 1990; MacDonald et al., 1995). Alcohol can be life threatening when heavy drinking follows an earlier period of moderate drinking, which depresses the vomiting response. People may poison themselves with an overdose that their bodies would normally throw up.

© Lon C. Diehl/PhotoEdit

Drinking disaster demo

Firefighters reenacted the trauma of an alcohol-related car accident, providing a memorable demonstration for these high school students. Alcohol consumption leads to feelings of invincibility, which become especially dangerous behind the wheel of a car.

Memory Disruption Alcohol can disrupt memory formation, and heavy drinking can also have long-term effects on the brain and cognition. In rats, at a developmental period corresponding to human adolescence, binge drinking contributes to nerve cell death and reduces the birth of new nerve cells. It also impairs the growth of synaptic connections (Crews et al., 2006, 2007). In humans, heavy drinking may lead to blackouts, in which drinkers are unable to recall people they met the night before or what they said or did while intoxicated. These blackouts result partly from the way alcohol suppresses REM sleep, which helps fix the day's experiences into permanent memories.

Reduced Self-Awareness and Self-Control In one experiment, those who consumed alcohol (rather than a placebo beverage) were doubly likely to be caught mind-wandering during a reading task, yet were *less* likely to notice that they zoned out (Sayette et al., 2009). Sometimes we mind-wander to give our brains a break, but unintentional zoning out—while driving, for example—can cause later regret, especially if we've endangered ourselves or others (Seli et al., 2016). Alcohol not only reduces self-awareness, it also produces a sort of “myopia” by focusing attention on an arousing situation (say, provocation) and distracting it from normal inhibitions and future

consequences (Giancola et al., 2010; Hull & Bond, 1986; Steele & Josephs, 1990).

Reduced self-awareness may help explain why people who want to suppress their awareness of failures or shortcomings are more likely to drink than are those who feel good about themselves. Losing a business deal, a game, or a romantic partner sometimes elicits a drinking binge.

Expectancy Effects As with other psychoactive drugs, expectations influence behavior. Expectations help explain why adolescents—presuming that alcohol will lift their spirits—sometimes drink when they’re upset and alone. Solitary drinking actually does not boost mood, but it does increase the likelihood of developing a substance use disorder (Creswell et al., 2014; Fairbairn & Sayette, 2014).

Simply *believing* we’re consuming alcohol can cause us to act out alcohol’s presumed influence (Christiansen et al., 2016; Moss & Albery, 2009). In a now-classic experiment, researchers gave Rutgers University men (who had volunteered for a study on “alcohol and sexual stimulation”) either an alcoholic or a nonalcoholic drink (Abrams & Wilson, 1983). (Both had strong tastes that masked any alcohol.) After watching an erotic movie clip, the men who *thought* they had consumed alcohol were more likely to report having strong sexual fantasies and feeling guilt-free. Being able to *attribute* their sexual responses to alcohol released their inhibitions—whether or not they had actually consumed any alcohol.

So, alcohol’s effect lies partly in that powerful sex organ, the mind. Fourteen “intervention studies” have educated college drinkers about that very point (Scott-Sheldon et al., 2014). Most participants came away with lower positive expectations of alcohol and reduced their drinking the ensuing month.

BARBITURATES Like alcohol, the [barbiturate](#) drugs, or *tranquilizers*, depress nervous system activity. Barbiturates such as Nembutal, Seconal, and Amytal are sometimes prescribed to induce sleep or reduce anxiety. In larger doses, they can impair memory and judgment. If combined with alcohol—as sometimes happens when people take a sleeping pill after an evening of heavy drinking—the total depressive effect on body functions can be lethal.

barbiturates drugs that depress central nervous system activity, reducing anxiety but impairing memory and judgment.

OPIATES The **opiates**—opium and its derivatives—also depress neural functioning. Opiates include *heroin* and also medically prescribed pain-relief *narcotics*, such as codeine, morphine and *methadone* (a synthetic opiate sometimes prescribed as a heroin substitute). As blissful pleasure replaces pain and anxiety, the user's pupils constrict, breathing slows, and lethargy sets in. Those who become addicted to this short-term pleasure may pay a long-term price: a gnawing craving for another fix, a need for progressively larger doses (as tolerance develops), and the extreme discomfort of withdrawal. When repeatedly flooded with an artificial opiate, the brain eventually stops producing *endorphins*, its own opiates. If the artificial opiate is then withdrawn, the brain will lack the normal level of these painkilling neurotransmitters. In recent years, more and more people have been unable or unwilling to tolerate this state and have paid an ultimate price—death by overdose (CDC, 2015).

opiates opium and its derivatives, such as morphine and heroin; depress neural activity, temporarily lessening pain and anxiety.

RETRIEVAL PRACTICE

RP-12 Can someone become “addicted” to shopping?

ANSWER: Unless it becomes compulsive or dysfunctional, simply having a strong interest in shopping is not the same as having a physical addiction to a drug. It typically does not involve obsessive craving in spite of known negative consequences.

RP-13 Alcohol, barbiturates, and opiates are all in a class of drugs called _____.

ANSWER: depressants

Stimulants

LOQ 3-14 What are *stimulants*, and what are their effects?

A **stimulant** excites neural activity and speeds up body functions. Pupils dilate, heart and breathing rates increase, and blood sugar levels rise, causing a drop in appetite. Energy and self-confidence also rise.

stimulants drugs (such as caffeine, nicotine, and the more powerful cocaine, amphetamines, methamphetamine, and Ecstasy) that excite neural activity and speed up body functions.

Vasca/Shutterstock

Stimulants include caffeine, nicotine, and the more powerful cocaine, *amphetamines*, *methamphetamine* (“speed”), and Ecstasy. People use stimulants to feel alert, lose weight, or boost mood or athletic performance. Some students may resort to stimulants in hopes of boosting their academic

performance. Unfortunately, such stimulants offer only modest benefits (Ilieva et al., 2015). Stimulants can also be addictive, as you may know if you are one of the many who use caffeine daily in your coffee, tea, soda, or energy drinks. Cut off from your usual dose, you may crash into fatigue, headaches, irritability, and depression (Silverman et al., 1992). A mild dose of caffeine typically lasts three or four hours, which—if taken in the evening—may impair sleep.

NICOTINE Cigarettes, e-cigarettes, and other tobacco products deliver highly addictive [nicotine](#). Imagine that cigarettes were harmless—except, once in every 25,000 packs, an occasional innocent-looking one is filled with dynamite instead of tobacco. Not such a bad risk of having your head blown off. But with 250 million packs a day consumed worldwide, we could expect more than 10,000 gruesome daily deaths (more than three times the 9/11 terrorist fatalities each and every day)—surely enough to have cigarettes banned everywhere.²

nicotine a stimulating and highly addictive psychoactive drug in tobacco.

The lost lives from these dynamite-loaded cigarettes approximate those from today’s actual cigarettes. A teen-to-the-grave smoker has a 50 percent chance of dying from the habit, and each year, tobacco kills nearly 5.4 million of its 1.3 billion customers worldwide. (Imagine the outrage if terrorists took down an equivalent of 25 loaded jumbo jets today, let alone tomorrow and every day thereafter.) By 2030, annual tobacco deaths are expected to increase to 8 million. That means that *1 billion* twenty-first-century people may be killed by tobacco (WHO, 2012).

“There is an overwhelming medical and scientific consensus that cigarette smoking causes lung cancer, heart disease, emphysema, and other serious diseases in smokers. Smokers are far more likely to develop serious diseases, like lung cancer, than nonsmokers.”

Philip Morris Companies Inc., 1999

Tobacco products include cigarettes, cigars, chewing tobacco, pipe tobacco, snuff, and—most recently—e-cigarettes. E-cigarettes give users a jolt of nicotine without cancer-causing tar. As a result, their sale has boomed: Between 2011 and 2013, youth e-cigarette use tripled (Arrazola et al., 2015; Noland et al., 2016). But there is a downside: E-cigarettes deliver toxic chemicals and can increase one's chances of using conventional cigarettes (Barrington-Trimis et al., 2016; Farsalinos et al., 2014). And e-cigarettes seem not to help current smokers quit, as companies sometimes claim (Wang et al., 2015c).

For HIV patients who smoke, the virus is now much less lethal than the smoking (Helleberg et al., 2013).

Smoke a cigarette and nature will charge you 12 minutes—ironically, just about the length of time you spend smoking it (*Discover*, 1996). (Researchers don't yet know how e-cigarette smoking affects life expectancy.) Compared with nonsmokers, smokers' life expectancy is “at least 10 years shorter” (CDC, 2013b). Eliminating smoking would increase life expectancy more than any other preventive measure. Why, then, do so many people smoke?

Tobacco products are powerfully and quickly addictive. Attempts to quit even within the first weeks of smoking often fail (DiFranza, 2008). As with other addictions, smokers develop *tolerance*, and quitting causes withdrawal symptoms, including craving, insomnia, anxiety, irritability, and distractibility. Nicotine-deprived smokers trying to focus on a task experience a tripled rate of mind wandering (Sayette et al., 2010). When not craving a cigarette, they tend to underestimate the power of such cravings (Sayette et al., 2008).

“Smoking cures weight problems . . . eventually.”

Comedian-writer Steven Wright

All it takes to relieve the aversive state of a cigarette craving is a single puff. Within 7 seconds, a rush of nicotine will signal the central nervous system to release a flood of neurotransmitters ([FIGURE 3.20](#)). Epinephrine and norepinephrine will diminish appetite and boost alertness and mental

efficiency. Dopamine and opioids will temporarily calm anxiety and reduce sensitivity to pain (Ditre et al., 2011; Gavin, 2004). No wonder ex-smokers will sometimes, under stress, return to smoking—as did some 1 million Americans after the 9/11 terrorist attacks (Pesko, 2014). Ditto for people with major depressive disorder, who are more likely than others to see their efforts to quit go up in smoke (Zvolensky et al., 2015).

FIGURE 3.20 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.20 Where there's smoke . . . : The physiological effects of nicotine

Nicotine reaches the brain within 7 seconds, twice as fast as intravenous heroin. Within minutes, the amount in the blood soars.

“To cease smoking is the easiest thing I ever did; I ought to know because I’ve done it a thousand times.”

Mark Twain (1835–1910)

These rewards keep people smoking, even among the 3 in 4 smokers who wish they could stop (Newport, 2013). Each year, fewer than 1 in 7 who want

to quit will be able to resist. Even those who know they are committing slow-motion suicide may be unable to stop (Saad, 2002).

Nevertheless, repeated attempts seem to pay off. Half of all Americans who have ever smoked have quit, sometimes aided by a nicotine replacement drug and with encouragement from a counselor or support group. Some researchers argue that it is best to quit abruptly—to go “cold turkey” (Lindson-Hawley et al., 2016). Others suggest that success is equally likely whether smokers quit abruptly or gradually (Fiore et al., 2008; Lichtenstein et al., 2010). For those who endure, the acute craving and withdrawal symptoms gradually dissipate over the ensuing six months (Ward et al., 1997). After a year’s abstinence, only 10 percent will relapse in the next year (Hughes, 2010). These nonsmokers may live not only healthier but also happier lives. Smoking correlates with higher rates of depression, chronic disabilities, and divorce (Doherty & Doherty, 1998; Edwards & Kendler, 2012; Vita et al., 1998). Healthy living seems to add both years to life and life to years.

Humorist Dave Barry (1995) recalling why he smoked his first cigarette the summer he turned 15: “Arguments against smoking: ‘It’s a repulsive addiction that slowly but surely turns you into a gasping, gray-skinned, tumor-ridden invalid, hacking up brownish gobs of toxic waste from your one remaining lung.’ Arguments for smoking: ‘Other teenagers are doing it.’ Case closed! Let’s light up!”

RETRIEVAL PRACTICE

RP-14 What withdrawal symptoms should your friend expect when she finally decides to quit smoking?

ANSWER: Nicotine-withdrawal symptoms include strong cravings, insomnia, anxiety, irritability, distractibility, and difficulty concentrating. However, if your friend sticks with it, the craving and withdrawal symptoms will gradually dissipate over about six months.

COCAINE [Cocaine](#) is a powerful and addictive stimulant derived from the

coca plant. The recipe for Coca-Cola originally included an extract of that plant, creating a cocaine tonic for tired elderly people. Between 1896 and 1905, Coke was indeed “the real thing.” But no longer. Cocaine is now snorted, injected, or smoked (sometimes as the street drug *crack cocaine*, a faster-working crystallized form that produces a briefer but more intense high, followed by a more intense crash). It enters the bloodstream quickly, producing a rush of euphoria that depletes the brain’s supply of the neurotransmitters dopamine, serotonin, and norepinephrine ([FIGURE 3.21](#)). Within the hour, a crash of agitated depression follows as the drug’s effect wears off. After several hours, the craving for more wanes, only to return several days later (Gawin, 1991).

cocaine a powerful and addictive stimulant derived from the coca plant; produces temporarily increased alertness and euphoria.

FIGURE 3.21 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.21 Cocaine euphoria and crash

In situations that trigger aggression, ingesting cocaine may heighten reactions. Caged rats fight when given foot shocks, and they fight even more when given cocaine *and* foot shocks. Likewise, humans who voluntarily ingest high doses of cocaine in laboratory experiments impose higher shock levels on a presumed opponent than do those receiving a placebo (Licata et al., 1993). Cocaine use may also lead to emotional disturbances, suspiciousness, convulsions, cardiac arrest, or respiratory failure.

Cocaine’s psychological effects depend in part on the dosage and form

consumed, but the situation and the user's expectations and personality also play a role. Given a placebo, cocaine users who *thought* they were taking cocaine often had a cocaine-like experience (Van Dyke & Byck, 1982).

In national surveys, 2.5 percent of U.S. high school seniors and 6 percent of British 18- to 24-year-olds reported having tried cocaine during the past year (ACMD, 2009; Johnston et al., 2017). Of those, nearly half had smoked crack.

“Cocaine makes you a new man. And the first thing that new man wants is more cocaine.”

Comedian George Carlin (1937–2008)

METHAMPHETAMINE [Amphetamines](#) stimulate neural activity. As body functions speed up, the user's energy rises and mood soars. Amphetamines are the parent drug for the highly addictive [methamphetamine](#), which is chemically similar but has greater effects (NIDA, 2002, 2005).

Methamphetamine triggers the release of the neurotransmitter dopamine, which stimulates brain cells that enhance energy and mood, leading to eight hours or so of heightened energy and euphoria. Its aftereffects may include irritability, insomnia, hypertension, seizures, social isolation, depression, and occasional violent outbursts (Homer et al., 2008). Over time, methamphetamine may reduce baseline dopamine levels, leaving the user with continuing depressed functioning.

amphetamines drugs that stimulate neural activity, causing accelerated body functions and associated energy and mood changes.

methamphetamine a powerfully addictive drug that stimulates the central nervous system, with accelerated body functions and associated energy and mood changes; over time, appears to reduce baseline dopamine levels.

Multnomah County Sheriff's Office

Dramatic drug-induced decline

In the 18 months between these two mug shots, this woman's methamphetamine addiction led to obvious physical changes.

ECSTASY Ecstasy, a street name for MDMA

(methylenedioxymethamphetamine, also known in its powder form as *Molly*), is both a stimulant and a mild hallucinogen. As an amphetamine derivative, Ecstasy triggers dopamine release, but its major effect is releasing stored serotonin and blocking its reuptake, thus prolonging serotonin's feel-good flood (Braun, 2001). Users feel the effect about a half-hour after taking an Ecstasy pill. For 3 or 4 hours, they experience high energy, emotional elevation, and (given a social context) connectedness with those around them ("I love everyone!").

Ecstasy (MDMA) a synthetic stimulant and mild hallucinogen. Produces euphoria and social intimacy, but with short-term health risks and longer-term harm to serotonin-producing neurons and to mood and cognition.

During the 1990s, Ecstasy's popularity soared as a "club drug" taken at nightclubs and all-night dance parties (Landry, 2002). The drug's popularity crosses national borders, with an estimated 60 million tablets consumed annually in Britain (ACMD, 2009). There are, however, reasons not to be ecstatic about Ecstasy. One is its dehydrating effect, which—when combined

with prolonged dancing—can lead to severe overheating, increased blood pressure, and death. Another is that long-term, repeated leaching of brain serotonin can damage serotonin-producing neurons, leading to decreased output and increased risk of permanently depressed mood (Croft et al., 2001; McCann et al., 2001; Roiser et al., 2005). Ecstasy also suppresses the immune system, impairs memory, slows thought, and disrupts sleep by interfering with serotonin’s control of the circadian clock (Laws & Kokkalis, 2007; Schilt et al., 2007; Wagner et al., 2012b). Ecstasy delights for the night but dispirits the morrow.

Hallucinogens

LOQ 3-15 What are *hallucinogens*, and what are their effects?

Dale Sparks/AP Images

The hug drug

MDMA, known as Ecstasy, produces a euphoric high and feelings of intimacy. But repeated use can destroy serotonin-producing neurons, impair memory, and permanently deflate mood.

Hallucinogens distort perceptions and evoke sensory images in the absence of sensory input (which is why these drugs are also called *psychedelics*, meaning “mind-manifesting”). Some, such as LSD and MDMA (Ecstasy), are synthetic. Others, including the mild hallucinogen marijuana, are natural

substances.

hallucinogens psychedelic (“mind-manifesting”) drugs, such as LSD, that distort perceptions and evoke sensory images in the absence of sensory input.

Whether provoked to hallucinate by drugs, loss of oxygen, or extreme sensory deprivation, the brain hallucinates in basically the same way (Siegel, 1982). The experience typically begins with simple geometric forms, such as a lattice, cobweb, or spiral. The next phase consists of more meaningful images; some may be superimposed on a tunnel or funnel, others may be replays of past emotional experiences. Brain scans of people on an LSD trip reveal that their visual cortex becomes hypersensitive and strongly connected to their brain’s emotion centers (Carhart-Harris et al., 2016). As the hallucination peaks, people frequently feel separated from their body and experience dreamlike scenes. Their sense of self dissolves, which also dissolves the border between themselves and the external world (Lebedev et al., 2015).

These sensations are strikingly similar to the [near-death experience](#), an altered state of consciousness reported by about 10 to 15 percent of those revived from cardiac arrest (Agrillo, 2011; Greyson, 2010; Parnia et al., 2014). Many describe visions of tunnels ([FIGURE 3.22](#)), bright lights or beings of light, a replay of old memories, and out-of-body sensations (Siegel, 1980). These experiences can later enhance spirituality and promote feelings of personal growth (Khanna & Greyson, 2014, 2015). Given that oxygen deprivation and other insults to the brain are known to produce hallucinations, it is difficult to resist wondering whether a brain under stress manufactures the near-death experience. During epileptic seizures and migraines, people may experience similar hallucinations of geometric patterns (Billock & Tsou, 2012). So have solitary sailors and polar explorers while enduring monotony, isolation, and cold (Suedfeld & Mocellin, 1987). The philosopher-neuroscientist Patricia Churchland (2013, [p. 70](#)) surmises that such experiences represent “neural funny business.”

near-death experience an altered state of consciousness reported after a

close brush with death (such as cardiac arrest); often similar to drug-induced hallucinations.

FIGURE 3.22 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
NUMAX3D/Shutterstock

FIGURE 3.22 Near-death vision or hallucination?

Psychologist Ronald Siegel (1977) reported that people under the influence of hallucinogenic drugs often see “a bright light in the center of the field of vision. . . . The location of this point of light create[s] a tunnel-like perspective.” This is very similar to others’ near-death experiences.

LSD Albert Hofmann, a chemist, created—and on one Friday afternoon in April 1943 accidentally ingested—**LSD** (lysergic acid diethylamide). The result—“an uninterrupted stream of fantastic pictures, extraordinary shapes with intense, kaleidoscopic play of colors”—reminded him of a childhood mystical experience that had left him longing for another glimpse of “a miraculous, powerful, unfathomable reality” (Siegel, 1984; Smith, 2006).

LSD a powerful hallucinogenic drug; also known as acid (*lysergic acid diethylamide*).

The emotions of an LSD (or *acid*) trip vary from euphoria to detachment to panic. Users’ mood and expectations (their “high hopes”) color the

emotional experience, but the perceptual distortions and hallucinations have some commonalities.

MARIJUANA The straight dope on marijuana: Marijuana leaves and flowers contain **THC** (delta-9-tetrahydrocannabinol). Whether smoked (getting to the brain in about 7 seconds) or eaten (traveling at a slower, unpredictable rate), THC produces a mix of effects.

THC the major active ingredient in marijuana; triggers a variety of effects, including mild hallucinations.

It is usually classified as a mild hallucinogen because it amplifies sensitivity to colors, sounds, tastes, and smells. But like alcohol, marijuana also relaxes, disinhibits, and may produce a euphoric high. Both alcohol and marijuana impair the motor coordination, perceptual skills, and reaction time necessary for safely operating an automobile or other machine. “THC causes animals to misjudge events,” reported Ronald Siegel (1990, [p. 163](#)). “Pigeons wait too long to respond to buzzers or lights that tell them food is available for brief periods; and rats turn the wrong way in mazes.”

Synthetic marijuana (*K2*, also called *Spice*) mimics THC. Its harmful side effects can include agitation and hallucinations (Fattore, 2016; Sherif et al., 2016).

Marijuana and alcohol also differ. The body eliminates alcohol within hours. THC and its by-products linger in the body for more than a week, which means that regular users experience less abrupt withdrawal and may achieve a high with smaller-than-usual drug amounts. This is the opposite of typical tolerance, in which repeat users need larger doses to feel the same effect.

After considering more than 10,000 scientific reports, the U.S. National Academies of Sciences, Engineering, and Medicine (2017) concluded that marijuana use

- alleviates chronic pain and chemotherapy-related nausea,
- is not associated with tobacco-related cancers, such as lung cancer,
- is predictive of increased risk of traffic accidents, chronic bronchitis, psychosis, social anxiety disorder, and suicidal thoughts, and
- likely contributes to impaired attention, learning, and memory, and possibly to academic underachievement.

A marijuana user's experience can vary with the situation. If the person feels anxious or depressed, marijuana may intensify the feelings. The more often the person uses marijuana, especially during adolescence, the greater the risk of anxiety, depression, psychosis, or addiction (Bambico et al., 2010; Hurd et al., 2013; Volkow et al., 2016).

Some U.S. states and countries have passed laws legalizing the possession of small quantities of marijuana. Greater legal acceptance may help explain why Americans' marijuana use nearly doubled between 2013 and 2016, from 7 to 13 percent (McCarthy, 2016).

* * *

Despite their differences, the psychoactive drugs summarized in [TABLE 3.5](#) share a common feature: They trigger negative aftereffects that offset their immediate positive effects and grow stronger with repetition. This helps explain both tolerance and withdrawal.

TABLE 3.5

A Guide to Selected Psychoactive Drugs

Drug	Type	Pleasurable Effects	Negative Aftereffects
<i>Alcohol</i>	Depressant	Initial high followed by relaxation and disinhibition	Depression, memory loss, organ damage, impaired reactions
<i>Heroin</i>	Depressant	Rush of euphoria,	Depressed physiology,

		relief from pain	agonizing withdrawal
<i>Caffeine</i>	Stimulant	Increased alertness and wakefulness	Anxiety, restlessness, and insomnia in high doses; uncomfortable withdrawal
<i>Nicotine</i>	Stimulant	Arousal and relaxation, sense of well-being	Heart disease, cancer
<i>Cocaine</i>	Stimulant	Rush of euphoria, confidence, energy	Cardiovascular stress, suspiciousness, depressive crash
<i>Methamphetamine</i>	Stimulant	Euphoria, alertness, energy	Irritability, insomnia, hypertension, seizures
<i>Ecstasy (MDMA)</i>	Stimulant; mild hallucinogen	Emotional elevation, disinhibition	Dehydration, overheating, depressed mood, impaired cognitive and immune functioning
<i>LSD</i>	Hallucinogen	Visual “trip”	Risk of panic
<i>Marijuana (THC)</i>	Mild hallucinogen	Enhanced sensation, relief of pain, distortion of time, relaxation	Impaired learning and memory, increased risk of psychological disorders

RETRIEVAL PRACTICE

RP-15 “How strange would appear to be this thing that men call pleasure! And how curiously it is related to what is thought to be its opposite, pain! . . . Wherever the one is found, the other follows up behind.”

Plato, *Phaedo*, fourth century B.C.E.

How does this pleasure-pain description apply to the repeated use of psychoactive drugs?

ANSWER: Psychoactive drugs create pleasure by altering brain chemistry. With repeated use of the drug, the user develops tolerance and needs more of the drug to achieve the desired effect. (Marijuana is an exception.) Discontinuing use of the substance then produces painful or psychologically unpleasant withdrawal symptoms.

To review the basic psychoactive drugs and their actions, and to play the role of experimenter as you administer drugs and observe their effects, visit **PsychSim 6: Your Mind on Drugs**.

Influences on Drug Use

LOQ 3-16 Why do some people become regular users of consciousness-altering drugs?

Drug use by North American youth increased during the 1970s. Then, with increased drug education and a more realistic and deglamorized media depiction of taking drugs, drug use declined sharply (except for a small rise in the mid-1980s). After the early 1990s, the cultural antidrug voice softened, and some drugs for a time were again glamorized in music and films. Consider, for example, historical trends in the use of marijuana:

- In the University of Michigan’s annual survey of 15,000 U.S. high school

seniors, the proportion who said there is “great risk” in regular marijuana use rose from 35 percent in 1978 to 79 percent in 1991, then retreated to 32 percent in 2015 (Johnston et al., 2017).

- After peaking in 1978, marijuana use by U.S. high school seniors declined through 1992, then rose, but has recently been holding steady (see [FIGURE 3.23](#)). Among Canadian 15- to 24-year-olds, 23 percent report using marijuana monthly, weekly, or daily (Health Canada, 2012).

FIGURE 3.23 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.23 Trends in drug use

The percentage of U.S. high school seniors who said they had used alcohol, marijuana, or cocaine during the past 30 days largely declined from the late 1970s to 1992, when it partially rebounded for a few years. (Data from Johnston et al., 2017; Miech et al., 2016.)

For some adolescents, occasional drug use represents thrill seeking. Yet why do some adolescents, but not others, become regular drug users? In search of answers, researchers have engaged biological, psychological, and social-cultural levels of analysis.

Biological Influences

Some people may be biologically vulnerable to particular drugs. For example, evidence accumulates that heredity influences some aspects of substance use problems, especially those appearing by early adulthood (Crabbe, 2002):

- If an identical rather than fraternal twin is diagnosed with alcohol use disorder, the other twin is at increased risk for alcohol problems (Kendler

et al., 2002). In marijuana use, too, identical twins more closely resemble each other than do fraternal twins.

- Researchers have identified genes associated with alcohol use disorder, and they are seeking genes that contribute to tobacco addiction (Stacey et al., 2012). These culprit genes seemingly produce deficiencies in the brain's natural dopamine reward system: While triggering temporary dopamine-produced pleasure, the addictive drugs disrupt normal dopamine balance. Studies of how drugs reprogram the brain's reward systems raise hopes for anti-addiction drugs that might block or blunt the effects of alcohol and other drugs (Miller, 2008; Wilson & Kuhn, 2005).

Warning signs of alcohol use disorder:

- Drinking binges
- Craving alcohol
- Use results in unfulfilled work, school, or home tasks
- Failing to honor a resolve to drink less
- Continued use despite health risk
- Avoiding family or friends when drinking
- Biological influences on drug use extend to other drugs as well. One study tracked 18,115 Swedish adoptees. Those with drug-abusing biological parents were at doubled risk of drug abuse, indicating a genetic influence. But then those with drug-abusing adoptive siblings also had a doubled risk of drug abuse, indicating an environmental influence (Kendler et al., 2012). So, what might those environmental influences be?

See the **Video: Twin Studies** for a helpful tutorial animation about this type of research design.

Psychological and Social-Cultural Influences

Throughout this text, you will see that biological, psychological, and social-cultural factors interact to produce behavior. So, too, with problematic drug use ([FIGURE 3.24](#)). One psychological factor that has appeared in studies of youth and young adults is the feeling that life is meaningless and directionless (Newcomb & Harlow, 1986). This feeling is common among school dropouts who subsist without job skills, without privilege, and with

little hope.

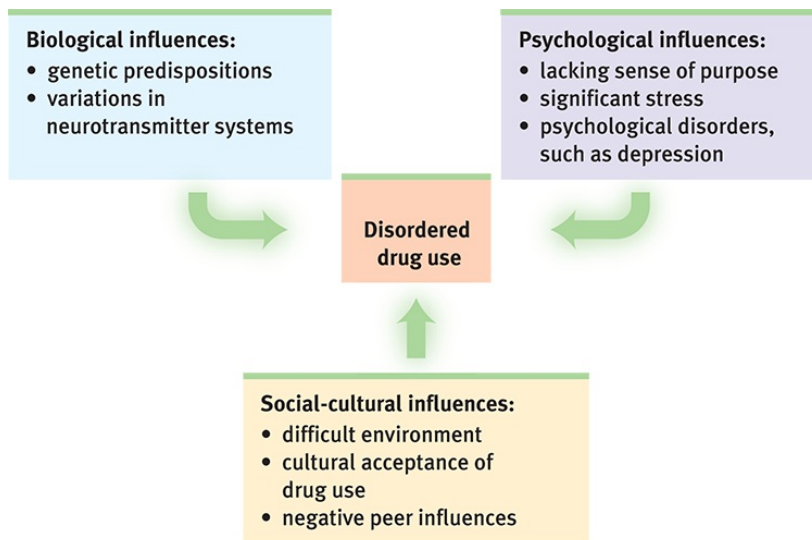

FIGURE 3.24 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.24 Levels of analysis for disordered drug use

The biopsychosocial approach enables researchers to investigate disordered drug use from complementary perspectives.

Sometimes the psychological influence is obvious. Many heavy users of alcohol, marijuana, and cocaine have experienced significant stress or failure and are depressed. Girls with a history of depression, eating disorders, or sexual or physical abuse are at increased risk for problematic substance use. So are youth undergoing school or neighborhood transitions (CASA, 2003; Logan et al., 2002). College and university students who have not yet achieved a clear identity are also at greater risk (Bishop et al., 2005). By temporarily dulling the pain of self-awareness, psychoactive drugs may offer a way to avoid coping with depression, anger, anxiety, or insomnia. (As [Chapter 7](#) explains, behavior is often controlled more by its immediate consequences than by its later ones.)

Smoking usually begins during early adolescence. (If you are in college or university, and the cigarette manufacturers haven't yet made you their devoted customer, they almost surely never will.) Adolescents, self-conscious and often thinking the world is watching their every move, are vulnerable to smoking's allure. They may first light up to imitate glamorous celebrities, to project a mature image, to handle stress, or to get the social reward of acceptance by other smokers (Cin et al., 2007; DeWall & Pond, 2011; Tickle et al., 2006). Mindful of these tendencies, cigarette companies have

effectively modeled smoking with themes that appeal to youths: attractiveness, independence, adventurousness, social approval (Surgeon General, 2012). Typically, teens who start smoking also have friends who smoke, who suggest its pleasures and offer them cigarettes (Rose et al., 1999). Among teens whose parents and best friends are nonsmokers, the smoking rate is close to zero (Moss et al., 1992; also see [FIGURE 3.25](#)).

FIGURE 3.25 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 3.25 Peer influence

Kids don't smoke if their friends don't (Philip Morris, 2003). A correlation-causation question: Does the close link between teen smoking and friends' smoking reflect peer influence? Teens seeking similar friends? Or both?

Pictorial Press Ltd/Alamy

Nic-A-Teen

Virtually nobody starts smoking past the vulnerable teen years. Eager to hook customers whose addiction will give them business for years to

come, cigarette companies target teens. Portrayals of smoking by popular actors, such as Scarlett Johansson in *Hail, Caesar!*, tempt teens to imitate.

Rates of drug use also vary across cultural and ethnic groups. One survey of European teens found that lifetime marijuana use ranged from 5 percent in Norway to more than eight times higher in the Czech Republic (Romelsjö et al., 2014). Independent U.S. government studies of drug use in households and among high schoolers nationwide reveal that African-American teens have sharply lower rates of drinking, smoking, and cocaine use (Johnston et al., 2007). Alcohol and other drug addiction rates have also been low among actively religious people, with extremely low rates among Orthodox Jews, Mormons, Mennonites, and the Amish (DeWall et al., 2014; Salas-Wright et al., 2012).

Whether in cities or rural areas, peers influence attitudes about substance use. They also throw the parties and provide (or don't provide) the drugs. If an adolescent's friends use drugs, the odds are that he or she will, too. If the friends do not, the opportunity may not even arise. Teens who come from happy families, who do not begin drinking before age 15, and who do well in school tend not to use drugs, largely because they rarely associate with those who do (Bachman et al., 2007; Hingson et al., 2006; Odgers et al., 2008).

Peer influence is more than what friends do or say. Adolescents' expectations—what they *believe* friends are doing and favoring—influence their behavior (Vitória et al., 2009). One study surveyed sixth graders in 22 U.S. states. How many believed their friends had smoked marijuana? About 14 percent. How many of those friends acknowledged doing so? Only 4 percent (Wren, 1999). University students are not immune to such misperceptions: Drinking dominates social occasions partly because students overestimate their peers' enthusiasm for alcohol and underestimate their views of its risks (Prentice & Miller, 1993; Self, 1994) ([TABLE 3.6](#)). When students' overestimates of peer drinking are corrected, alcohol use often subsides (Moreira et al., 2009).

TABLE 3.6

Facts About “Higher” Education

- College and university students drink more alcohol than their

nonstudent peers and exhibit 2.5 times the general population's rate of substance abuse.

- Fraternity and sorority members report nearly twice the binge-drinking rate of nonmembers.
- Since 1993, campus smoking rates have declined, alcohol use has been steady, and abuse of prescription opioids, stimulants, tranquilizers, and sedatives has increased, as has marijuana use.

Source: NCASA, 2007.

People whose beginning use of drugs was influenced by their peers are more likely to stop using when friends stop or their social network changes (Chassin & MacKinnon, 2015). One study that followed 12,000 adults over 32 years found that smokers tend to quit in clusters (Christakis & Fowler, 2008). Within a social network, the odds of a person quitting increased when a spouse, friend, or co-worker stopped smoking. Similarly, most soldiers who engaged in problematic drug use while in Vietnam ceased their drug use after returning home (Robins et al., 1974).

As always with correlations, the traffic between friends' drug use and our own may be two-way: Our friends influence us. Social networks matter. But we also select as friends those who share our likes and dislikes.

What do the findings on drug use suggest for drug prevention and treatment programs? Three channels of influence seem possible:

- Educate young people about the long-term costs of a drug's temporary pleasures.
- Help young people find other ways to boost their self-esteem and discover their purpose in life.
- Attempt to modify peer associations or to "inoculate" youth against peer pressures by training them in refusal skills.

© Jason Love

People rarely abuse drugs if they understand the physical and psychological costs, feel good about themselves and the direction their lives are taking, and are in a peer group that disapproves of using drugs. These educational, psychological, and social-cultural factors may help explain why 26 percent of U.S. high school dropouts, but only 6 percent of those with a postgraduate education, report smoking (CDC, 2011).

Substance use disorders don't discriminate; they affect the rich and the poor; they affect all ethnic groups. This is a public health crisis, but we do have solutions.

U.S. Surgeon General Vivek Murthy, 2016

RETRIEVAL PRACTICE

RP-16 Why do tobacco companies try so hard to get customers hooked as teens?

ANSWER: Nicotine is powerfully addictive, and those who start paving the neural pathways when young may find it very hard to stop using it. As a result, tobacco companies may have lifelong customers. Moreover, evidence suggests that if cigarette manufacturers haven't hooked customers by early adulthood, they most likely won't.

RP-17 Studies have found that people who begin drinking in their early teens are much more likely to develop alcohol use disorder than those who begin at age 21 or after. What possible explanations might there be for this correlation?

ANSWER: Possible explanations include (a) biological factors (a person could have a biological predisposition to both early use and later abuse, or alcohol use could modify a person's neural pathways); (b) psychological factors (early use could establish taste preferences for alcohol); and (c) social-cultural factors (early use could influence enduring habits, attitudes, activities, or peer relationships that could foster alcohol use disorder).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

After continued use of a psychoactive drug, the drug user needs to take larger doses to get the desired effect. This is referred to as _____.

The depressants include alcohol, barbiturates,

- a. and opiates.
- b. cocaine, and morphine.
- c. caffeine, nicotine, and marijuana.
- d. and amphetamines.

Why might alcohol make a person more helpful *or* more aggressive?

Long-term use of Ecstasy can

- a. depress sympathetic nervous system activity.
- b. deplete the brain's supply of epinephrine.
- c. deplete the brain's supply of dopamine.
- d. damage serotonin-producing neurons.

Near-death experiences are strikingly similar to the experiences evoked by _____.

Use of marijuana

- a. impairs motor coordination, perception, reaction time, and memory.
- b. inhibits people's emotions.
- c. leads to dehydration and overheating.
- d. stimulates brain cell development.

An important psychological contributor to drug use is

- a. inflated self-esteem.
- b. the feeling that life is meaningless and directionless.
- c. genetic predispositions.
- d. overprotective parents.

Reflections on Nature, Nurture, and Their Interaction

What makes you you? In important ways, we are each unique. We are each a one-of-a-kind package of looks, language, personality, interests, and cultural background.

We are also the leaves of one tree. Our human family shares not only a common biological heritage—cut us and we bleed—but also common behavioral tendencies. Our shared brain architecture disposes us to sense the world, develop language, and feel hunger through identical mechanisms. Whether we live in the Arctic or the Atacama desert, we prefer sweet tastes to sour. We divide the color spectrum into similar colors. And we feel drawn to behaviors that produce and protect offspring.

Our kinship also appears in our social behaviors. Whether named Gonzales, Nkomo, Ahmadi, Smith, or Wong, we start fearing strangers at about eight months, and as adults we prefer the company of those with attitudes and attributes similar to our own. Coming from different parts of the globe, we know how to read one another's smiles and frowns. As members of one species, we affiliate, conform, return favors, punish offenses, organize hierarchies of status, and anguish over a child's death. A visitor from outer space could drop in anywhere and find humans dancing and feasting, singing and worshiping, playing sports and games, laughing and crying, living in families and forming groups. Taken together, such universal behaviors define our human nature.

What causes our striking diversity, and also our shared human nature? How much are our differences shaped by our differing genes? And how much by our environment—by every external influence, from maternal nutrition while in the womb to social support while nearing the tomb? To what extent are we formed by our upbringing? By our culture? By our current circumstances? By people's reactions to our genetic dispositions? By our own choices and efforts? This chapter tells the scientific story of how our genes (nature) and environments (nurture) together knit us.

Behavior Genetics: Predicting Individual Differences

LOQ LEARNING OBJECTIVE QUESTION 4-1 What are

chromosomes, DNA, genes, and the human genome? How do behavior geneticists explain our individual differences?

So, if Beyoncé and Jay Z’s daughter, Blue Ivy, grows up to be a popular recording artist, should we attribute her musical talent to her “superstar genes”? To her growing up in a musically rich environment? To high expectations? Such questions intrigue [behavior geneticists](#), who study our differences and weigh the effects and the interplay of [heredity](#) and [environment](#).

behavior genetics the study of the relative power and limits of genetic and environmental influences on behavior.

heredity the genetic transfer of characteristics from parents to offspring.

environment every nongenetic influence, from prenatal nutrition to the people and things around us.

A Thousand Words Photography by Erica Corner

The nurture of nature

Parents everywhere wonder: Will my baby grow up to be peaceful or aggressive? Plain or attractive? Successful or struggling at every step? What comes built in, and what is nurtured—and how? Research reveals that nature and nurture together shape our development—every step of the way.

Genes: Our Codes for Life

Behind the story of our body and of our brain—surely the most awesome thing on our little planet—is the heredity that interacts with our experience to create both our universal nature and our individual and social diversity. Barely more than a century ago, few would have guessed that every cell nucleus in your body contains the genetic master code for your entire body. It's as if every room in Dubai's Burj Khalifa (the world's tallest building) contained a book detailing the architect's plans for the entire structure. The plans for your own book of life run to 46 chapters—23 donated by your mother's egg and 23 by your father's sperm. Each of these 46 chapters, called a **chromosome**, is composed of a coiled chain of the molecule **DNA (deoxyribonucleic acid)**. **Genes**, small segments of the giant DNA molecules, form the words of those chapters (**FIGURE 4.1**). Altogether, you have some 20,000 genes, which are either active (*expressed*) or inactive. Environmental events “turn on” genes, rather like hot water enabling a tea bag to express its flavor. When turned on, genes provide the code for creating *protein molecules*, our body's building blocks.

chromosomes threadlike structures made of DNA molecules that contain the genes.

DNA (deoxyribonucleic acid) a complex molecule containing the genetic information that makes up the chromosomes.

genes the biochemical units of heredity that make up the chromosomes; segments of DNA capable of synthesizing proteins.

FIGURE 4.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 4.1 The life code

The nucleus of every human cell contains chromosomes, each of which is made up of two strands of DNA connected in a double helix. Genes are DNA segments that, when expressed (turned on) direct the development of proteins that influence a person's individual development.

Genetically speaking, every other human is nearly your identical twin. Human **genome** researchers have discovered a common sequence within human DNA. This shared genetic profile is what makes us humans, rather than tulips, bananas, or chimpanzees.

genome the complete instructions for making an organism, consisting of all the genetic material in that organism's chromosomes.

"Thanks for almost everything, Dad."

The New Yorker Collection, 1999 Danny
Shanahan from cartoonbank.com.
All Rights Reserved.

Yet we aren't all that different from our chimpanzee cousins. At a genetic level, humans and chimpanzees are 96 percent identical (Mikkelsen et al., 2005). At "functionally important" DNA sites, this number reaches 99.4 percent (Wildman et al., 2003)! Yet that wee 0.6 percent difference matters. It took a human, Shakespeare, to do what a chimpanzee cannot—intricately weave 17,677 words into literary masterpieces.

Small differences matter among other species, too. Common chimpanzees and bonobos resemble each other in many ways. They should—their genomes differ by much less than 1 percent. But they display markedly differing behaviors. Chimpanzees are aggressive and male dominated. Bonobos are peaceable and female led.

"We share half our genes with the banana."

**Evolutionary biologist Robert May, president of Britain's Royal Society,
2001**

The occasional variations found at particular gene sites in human DNA fascinate geneticists and psychologists. Slight person-to-person variations from the common pattern give clues to our uniqueness—why one person has a disease that another does not, why one person is tall and another short, why one is anxious and another calm.

“Your DNA and mine are 99.9 percent the same. . . . At the DNA level, we are clearly all part of one big worldwide family.”

Francis Collins, Human Genome Project director, 2007

Most of our traits have complex genetic roots. How tall you are, for example, reflects the size of your face, vertebrae, leg bones, and so forth—each of which may be influenced by different genes interacting with your specific environment. Traits such as intelligence, happiness, and aggressiveness are each similarly influenced by many genes. Indeed, one of the big take-home findings of today’s behavior genetics is that there is no single smart gene, gay (or straight) gene, or schizophrenia gene. Rather, our differing traits are influenced by “many genes of small effect” (Okbay et al., 2016; Plomin et al., 2016).

So, our many genes help explain both our shared human nature and our human diversity. But—another take-home finding—knowing our heredity tells only part of our story. To form us, environmental influences interact with our genetic predispositions.

RETRIEVAL PRACTICE

ANSWER: gene, chromosome, nucleus

Twin and Adoption Studies

LOQ 4-2 How do twin and adoption studies help us understand the effects and interactions of nature and nurture?

To scientifically tease apart the influences of heredity and environment, behavior geneticists could wish for two types of experiments. The first would control heredity while varying the home environment. The second would control the home environment while varying heredity. Although such experiments with human infants would be unethical, nature has done this

work for us.

See the **Video: Twin Studies** for a helpful tutorial animation.

Identical Versus Fraternal Twins

Identical (monozygotic) twins develop from a single fertilized egg that splits. Thus they are *genetically* identical—nature’s own human clones (**FIGURE 4.2**). Indeed, they are clones who share not only the same genes but the same conception and uterus, and usually the same birth date and cultural history. Two slight qualifications:

- Although identical twins have the same genes, they don’t always have the same *number of copies* of those genes repeated within their genome. That variation helps explain why one twin may have a greater risk for certain illnesses and disorders, including schizophrenia (Maiti et al., 2011).
- Most identical twins share a placenta during prenatal development, but one of every three sets has separate placentas. One twin’s placenta may provide slightly better nourishment, which may contribute to a few identical twin differences (Marceau et al., 2016; van Beijsterveldt et al., 2016).

FIGURE 4.2 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 4.2 Same fertilized egg, same genes; different eggs, different genes

Identical twins develop from a single fertilized egg, fraternal twins from two.

identical (monozygotic) twins develop from a single fertilized egg that splits in two, creating two genetically identical organisms.

Fraternal (dizygotic) twins develop from two separate fertilized eggs. As fetal partners, they share a prenatal environment, but they are genetically no more similar than ordinary brothers and sisters.

fraternal (dizygotic) twins develop from separate fertilized eggs. They are genetically no closer than ordinary brothers and sisters, but they share a prenatal environment.

Shared genes can translate into shared experiences. A person whose identical twin has *autism spectrum disorder*, for example, has about a 3 in 4 risk of being similarly diagnosed. If the affected twin is fraternal, the co-twin has about a 1 in 3 risk (Ronald & Hoekstra, 2011). To study the effects of genes and environments, several thousand medical and psychological researchers have studied nearly 15 million identical and fraternal twin pairs (Polderman et al., 2015).

Are genetically identical twins also *behaviorally* more similar than fraternal twins? Studies of thousands of twin pairs in Germany, Australia, and the United States have found that identical twins are much more alike in *extraversion* (outgoingness) and *neuroticism* (emotional instability) than are fraternal twins (Kandler, 2011; Laceulle et al., 2011; Loehlin, 2012). Genes also influence many specific behaviors. For example, compared with rates for fraternal twins, drinking and driving convictions are 12 times greater among those who have an identical twin with such a conviction (Beaver & Barnes, 2012). As identical twins grow older, their behaviors remain similar (McGue & Christensen, 2013).

Identical twins, more than fraternal twins, look alike. So, do people's responses to their looks account for their similarities? *No*. In a clever approach, researcher (and twin) Nancy Segal (2013; Segal et al., 2013) compared personality similarity between identical twins and unrelated look-alike pairs. Only the identical twins reported similar personalities. Other studies have shown that identical twins whose parents treated them alike (for example, dressing them identically) were not psychologically more alike than identical twins who were treated less similarly (Kendler et al., 1994; Loehlin & Nichols, 1976). In explaining individual differences, genes matter.

twinstrangers.com

Do look-alikes act alike?

Genetically unrelated look-alikes, such as these doppelgangers, tend not to have notably similar personalities (Segal, 2013).

Separated Twins

Imagine the following science fiction experiment: A mad scientist decides to separate identical twins at birth, then raise them in differing environments. Better yet, consider a *true* story:

In 1979, some time after divorcing, Jim Lewis awoke next to his second wife. Determined to make this marriage work, Jim made a habit of leaving love notes around the house. As he lay in bed he thought about others he had loved, including his son, James Alan, and his faithful dog, Toy.

Jim enjoyed spending part of the day in his basement woodworking shop building furniture, picture frames, and other items, including a white bench now circling a tree in his front yard. Jim also liked to drive his Chevy, watch stock-car racing, and drink Miller Lite beer.

Twins Lorraine and Levinia Christmas, driving to deliver Christmas presents to each other near Fritcham, England, collided (Shepherd, 1997).

Jim was basically healthy, except for occasional half-day migraine headaches and blood pressure that was a little high, perhaps related to his chain-smoking habit. He had become overweight a while back but had shed some of the pounds. Having undergone a vasectomy, he was done having children.

What was extraordinary about Jim Lewis, however, was that at that same moment (we are not making this up) there existed another man—also named Jim—for whom all these things (right down to the dog’s name) were also true.¹ This other Jim—Jim Springer—just happened, 38 years earlier, to have been his womb-mate. Thirty-seven days after their birth, these genetically identical twins were separated, adopted by blue-collar families, and raised with no contact or knowledge of each other’s whereabouts until the day Jim Lewis received a call from his genetic clone (who, having been told he had a twin, set out to find him).

Mona Friis Bertheussen/Moment Film

Identical twins are people two

Identical twin sisters Mia (left) and Alexandra (right), featured in the 2013 film *Twin Sisters*, were adopted to different families as infants and grew up worlds apart. The film shows Mia growing up in suburban California, Alexandra in a Norwegian village. Nevertheless, the twins share striking similarities, including a dislike of tomatoes, olives, and messy rooms, and a passion for chocolate.

One month later, the brothers became the first of many separated twin pairs tested by University of Minnesota psychologist Thomas Bouchard and his colleagues (Miller, 2012c). The brothers’ voice intonations and inflections were so similar that, hearing a playback of an earlier interview, Jim Springer guessed, “That’s me.” Wrong—it was Jim Lewis. Given tests measuring their personality, intelligence, heart rate, and brain waves, the Jim twins—despite 38 years of separation—were virtually as alike as the same person tested twice. Both married women named Dorothy Jane Scheckelburger. Okay, the last item is a joke. But as Judith Rich Harris (2006) has noted, it is hardly weirder than some other reported similarities.

Aided by media publicity, Bouchard (2009) and his colleagues located and

studied 74 pairs of identical twins raised apart. They continued to find similarities not only of tastes and physical attributes but also of personality, abilities, attitudes, interests, and even fears.

In Sweden, researchers identified 99 separated identical twin pairs and more than 200 separated fraternal twin pairs (Pedersen et al., 1988). Compared with equivalent samples of identical twins raised together, the separated identical twins had somewhat less identical personalities. Still, separated twins were more alike if genetically identical than if fraternal. And separation shortly after birth (rather than, say, at age 8) did not amplify their personality differences.

Stories of startling twin similarities have not impressed critics, who remind us that “the plural of *anecdote* is not *data*.” They note that if any two strangers were to spend hours comparing their behaviors and life histories, they would probably discover many coincidental similarities. If researchers created a control group of biologically unrelated pairs of the same age, sex, and ethnicity, who had not grown up together but who were as similar to one another in economic and cultural background as are many of the separated twin pairs, wouldn’t these pairs also exhibit striking similarities (Joseph, 2001)? Twin researchers have replied that separated fraternal twins do not exhibit similarities comparable to those of separated identical twins.

Bouchard’s famous twin research was, appropriately enough, conducted in Minneapolis, the “Twin City” (with St. Paul) and home to the Minnesota Twins baseball team.

Even the impressive data from personality assessments are clouded by the reunion of many of the separated twins some years before they were tested. Adoption agencies also tend to place separated twins in similar homes. Despite these criticisms, the striking twin-study results helped shift scientific thinking toward a greater appreciation of genetic influences.

Biological Versus Adoptive Relatives

For behavior geneticists, nature’s second real-life experiment—adoption—creates two groups: *genetic relatives* (biological parents and siblings) and

environmental relatives (adoptive parents and siblings). For personality or any other given trait, we can therefore ask whether adopted children are more like their biological parents, who contributed their genes, or their adoptive parents, who contribute a home environment. And while sharing that home environment, do adopted siblings come to share traits?

The stunning finding from studies of hundreds of adoptive families is that, apart from identical twins, people who grow up together, whether biologically related or not, do not much resemble one another in personality (McGue & Bouchard, 1998; Plomin, 2011; Rowe, 1990). In personality traits such as extraversion and agreeableness, for example, people who have been adopted are more similar to their *biological* parents than their caregiving adoptive parents.

The finding is important enough to bear repeating: *The normal range of environments shared by a family's children has little discernible impact on their personalities.* Two adopted children raised in the same home are no more likely to share personality traits with each other than with the child down the block.

Heredity shapes other primates' personalities, too. Macaque monkeys raised by foster mothers exhibited social behaviors that resemble their biological, rather than foster, mothers (Maestripieri, 2003).

Why are children in the same family so different? Why does shared family environment have so little effect on children's personalities? Is it because each sibling experiences unique peer influences and life events? Because sibling relationships ricochet off each other, amplifying their differences? Because siblings—despite sharing half their genes—have very different combinations of genes and may evoke very different kinds of parenting? Such questions fuel behavior geneticists' curiosity.

The genetic leash may limit the family environment's influence on personality, but it does not mean that adoptive parenting is a fruitless venture. As an adoptive parent, I [ND] especially find it heartening to know that parents do influence their children's attitudes, values, manners, politics, and faith (Kandler & Riemann, 2013). This was dramatically illustrated by separated identical twins Jack Yufe, raised a Jew, and Oskar Stöhr, a member of Germany's Hitler Youth. After later reuniting, Oskar mused to Jack: "If we had been switched, I would have been the Jew, and you would have been the Nazi" (Segal, 2005, [p. 70](#)). Parenting—and the cultural environments in

which parents place children—matters!

Moreover, child neglect and abuse and even parental divorce are rare in adoptive homes. (Adoptive parents are carefully screened; biological parents are not.) So it is not surprising that, despite a somewhat greater risk of psychological disorder, most adopted children thrive, especially when adopted as infants (Loehlin et al., 2007; van IJzendoorn & Juffer, 2006; Wierzbicki, 1993). Seven in eight adopted children have reported feeling strongly attached to one or both adoptive parents. As children of self-giving parents, they have grown up to be more self-giving and altruistic than average (Sharma et al., 1998). Many scored higher than their biological parents and raised-apart biological siblings on intelligence tests, and most grew into happier and more stable adults (Kendler et al., 2015b; van IJzendoorn et al., 2005). In one Swedish study, children adopted as infants grew up with fewer problems than were experienced by children whose biological mothers initially registered them for adoption but then decided to raise the children themselves (Bohman & Sigvardsson, 1990). *The bottom line:* Regardless of personality differences between adoptive family members, most adopted children benefit from adoption.

Siblings so different: Hermann Goering was outgoing, loved crowds, and became Hitler's right-hand man and founder of the Nazi Gestapo. His younger brother Albert Goering was quiet and reclusive, and worked to save Jews that brother Hermann's regime was killing (Brennan, 2010).

Charles Sykes/AP Photo

Nature or nurture or both?

When talent runs in families, as with Wynton Marsalis, Branford Marsalis, and Delfeayo Marsalis, how do heredity and environment together do their work?

Frederick Breedon IV/Getty Images; Ryan Anson/Bloomberg/Getty Images

Adoption matters

Country music singer Faith Hill and late Apple founder Steve Jobs both benefited from one of the biggest gifts of love: adoption.

RETRIEVAL PRACTICE

RP-2 How do researchers use twin and adoption studies to learn about psychological principles?

ANSWER: Researchers use twin and adoption studies to understand how much variation among individuals is due to genetic makeup and how much is due to environmental factors. Some studies compare the traits and behaviors of identical twins (same genes) and fraternal twins (different genes, as in any two siblings). They also compare adopted children with their adoptive and biological parents. Some studies compare traits and behaviors of twins raised together or separately.

Temperament and Heredity

LOQ 4-3 What have psychologists learned about temperament?

As most parents will tell you after having their second child, babies differ even before gulping their first breath. One aspect of personality—**temperament** (emotional reactivity and excitability)—is quickly apparent, and it is genetically influenced (Kandler et al., 2013; Raby et al., 2012). Identical twins, more than fraternal twins, often have similar temperaments (Fraley & Tancredy, 2012; Kandler et al., 2013). Temperament differences typically persist. The most emotionally reactive newborns tend also to be the most reactive 9-month-olds (Wilson & Matheny, 1986; Worobey & Blajda, 1989). Emotionally intense preschoolers tend to become relatively intense young adults (Larsen & Diener, 1987). In one study of more than 900 New Zealanders, emotionally reactive and impulsive 3-year-olds developed into somewhat more impulsive, aggressive, and conflict-prone 21-year-olds (Caspi, 2000).

temperament a person's characteristic emotional reactivity and intensity.

The genetic effect appears in physiological differences. Anxious, inhibited

infants have high and variable heart rates and a reactive nervous system. When facing new or strange situations, they become more physiologically aroused (Kagan & Snidman, 2004; Roque et al., 2012).

Consider how researchers have studied these issues by engaging online with **Immersive Learning: How Would You Know If Personality Runs in Our Genes?**

Heritability

LOQ 4-4 What is *heritability*, and how does it relate to individuals and groups?

So our biology helps form our personality. Yet asking whether our personality is more a product of our genes or our environment is like asking whether a playing field's size is more the result of its length or its width. We could, however, ask whether the different playing-field sizes are more the result of *differences* in their length or differences in their width. Similarly, we can ask whether person-to-person personality differences are influenced more by nature or by nurture.

Using twin and adoption studies, behavior geneticists can mathematically estimate the **heritability** of a trait—the extent to which variation among individuals in a group can be attributed to their differing genes. For many personality traits, heritability is about 40 percent; for general intelligence, heritability has been estimated at about 66 percent (Haworth et al., 2010; Turkheimer et al., 2014). This does *not* mean that *your* intelligence is 66 percent genetic. Rather, it means that genetic influence explains about 66 percent of the observed *variation among people*. We can never say what percentage of an *individual's* personality or intelligence is inherited. It makes no sense to say that your personality is due x percent to your heredity and y percent to your environment. This point is so often misunderstood that we repeat: Heritability refers to how much *differences among people* are due to genes.

heritability the proportion of variation among individuals in a group that we can attribute to genes. The heritability of a trait may vary, depending on the

range of populations and environments studied.

The heritability of intelligence varies from study to study. Consider humorist Mark Twain's (1835–1910) fictional idea of raising boys in barrels to age 12, feeding them through a hole. If we were to follow his suggestion, the boys would all emerge with lower-than-normal intelligence scores at age 12. Yet, given their equal environments, their test score differences could be explained only by their heredity. With the same environment, heritability—differences due to genes—would be near 100 percent.

As environments become more similar, heredity becomes the primary source of differences. If all schools were of uniform quality, all families equally loving, and all neighborhoods equally healthy, then heritability would *increase* (because differences due to environment would *decrease*). But consider the other extreme: If all people had similar heredities but were raised in drastically different environments (some in barrels, some in luxury homes), heritability would be much lower.

If genetic influences help explain variations in traits among individuals in a group, can the same be said of trait differences *between* groups? Not necessarily. Height is 90 percent heritable, yet nutrition (an environmental factor) rather than genes explains why, as a group, today's adults have grown (Floud et al., 2011). In 1850, the average American male stood 5 feet 7 inches (170 centimeters); in the 1980s, his counterpart stood 3 inches (7.5 centimeters) taller. The two groups differ, but not because human genes have changed in this eyeblink of time. Today's South Koreans, with their better diets, average 6 inches (15 centimeters) taller than today's genetically similar North Koreans (Johnson et al., 2009). Genes matter, but so does environment.

"The title of my science project is 'My Little Brother: Nature or Nurture.'"

The New Yorker Collection, 2003, Michael Shaw
from cartoonbank.com. All Rights Reserved.

As with height and weight, so with personality and intelligence scores: Heritable individual differences need not imply heritable group differences. And, if some *individuals* are genetically disposed to be more aggressive than others, that needn't explain why some *groups* are more aggressive than others. Putting people in a new social context can change their aggressiveness. Today's peaceful Scandinavians carry many genes inherited from their Viking warrior ancestors.

RETRIEVAL PRACTICE

RP-3 Those studying the *heritability* of a trait try to determine how much of the person-to-person variation in that trait among members of a specific group is due to their differing _____.

ANSWER: genes

For a 7-minute explanation of genes and environment, watch the **Video: Behavior Genetics**.

Gene-Environment Interaction

Among our similarities, the most important—the behavioral hallmark of our species—is our enormous adaptive capacity. Some human traits develop the same in virtually every environment. But other traits are expressed only in particular environments. Go barefoot for a summer and you will develop toughened, callused feet—a biological adaptation to friction. Meanwhile, your shod neighbor will remain a tenderfoot. The difference between the two of you is an effect of environment. But it is the product of a biological mechanism—adaptation. Our shared biology enables our developed diversity (Buss, 1991). Thus, to say that genes and experience are *both* important is true. But more precisely, they [interact](#). Just *how* our genes and our experiences interact to form us as unique individuals is one of the hottest topics in psychology today. Gene-environment interaction studies are revealing, for example, who is most at risk of permanent harm from stress or abuse and who is most likely to benefit from interventions (Manuck & McCaffery, 2014).

interaction the interplay that occurs when the effect of one factor (such as environment) depends on another factor (such as heredity).

Derek Storm/Splash News/Newscom

Genetic space exploration

In 2015, Scott (left) and Mark (right) Kelly embarked on a twin study that was literally out of this world. Scott spent 340 days orbiting the planet in

the International Space Station. His identical twin, Mark, remained on Earth. Both twins underwent the same physical and psychological testing. The study results will help scientists understand how genes and environment—in outer space and on Earth—interact.

“Heredity deals the cards; environment plays the hand.”

Psychologist Charles L. Brewer (1990)

Molecular Behavior Genetics

LOQ 4-5 How is molecular genetics research changing our understanding of the effects of nature and nurture?

Behavior geneticists have progressed beyond asking “Do genes influence behavior?” The newest frontier of behavior-genetic research draws on “bottom-up” [molecular genetics](#), which studies the molecular structure and function of genes.

molecular genetics the subfield of biology that studies the molecular structure and function of genes.

SEARCHING FOR SPECIFIC GENES INFLUENCING BEHAVIOR

Most human traits are influenced by teams of genes. For example, twin and adoption studies tell us that heredity influences body weight, but there is no single “obesity gene.” Some genes influence how quickly the stomach tells the brain, “I’m full” (Adetunji, 2014). Others might dictate how much fuel the muscles need, how many calories are burned off by fidgeting, and how efficiently the body converts extra calories into fat (Vogel, 1999). Genes typically are not solo players. So, one goal of [molecular behavior genetics](#) is to find some of the many genes that together orchestrate complex traits such as body weight, sexual orientation, and impulsivity.

molecular behavior genetics the study of how the structure and function of

genes interact with our environment to influence behavior.

EPIGENETICS: TRIGGERS THAT SWITCH GENES ON AND OFF

Genes can be either active (expressed, as hot water activates the tea bag) or inactive. **Epigenetics** (meaning “in addition to” or “above and beyond” genetics), studies the molecular mechanisms by which environments can trigger or block genetic expression. Genes are *self-regulating*. Rather than acting as blueprints that lead to the same result no matter the context, genes react. An African butterfly that is green in summer turns brown in fall, thanks to a temperature-controlled genetic switch. The same genes that produced green in one situation will produce brown in another.

epigenetics “above” or “in addition to” (*epi*) genetics; the study of environmental influences on gene expression that occur without a DNA change.

Our experiences also create *epigenetic marks*, which are often organic methyl molecules attached to part of a DNA strand (**FIGURE 4.3**). If a mark instructs the cell to ignore any gene present in that DNA segment, those genes will be “turned off”—they will prevent the DNA from producing the proteins normally coded by that gene. As one geneticist explained, “Things written in pen you can’t change. That’s DNA. Things written in pencil you can. That’s epigenetics” (Reed, 2012).

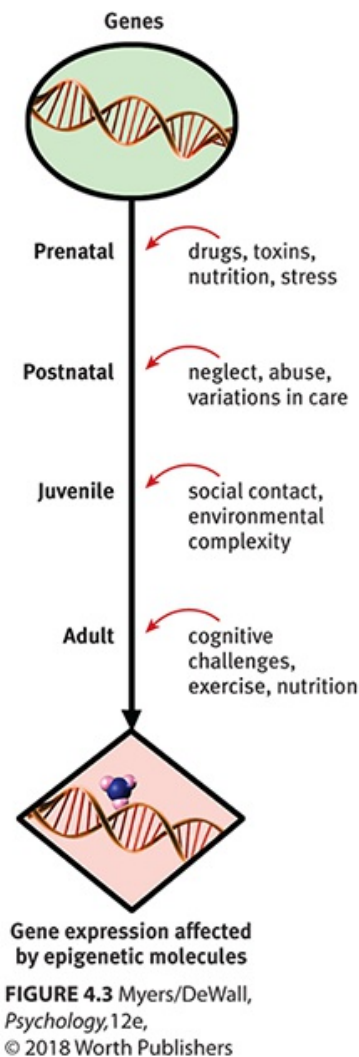

FIGURE 4.3 Epigenetics influences gene expression

Beginning in the womb, life experiences lay down *epigenetic marks*—often organic methyl molecules—that can influence the expression of any gene in the DNA segment they affect. (Research from Champagne, 2010.)

Environmental factors such as diet, drugs, and stress can affect the epigenetic molecules that regulate gene expression. Mother rats normally lick their infants. Deprived of this licking in experiments, infant rats had more epigenetic molecules blocking access to their brain’s “on” switch for developing stress hormone receptors. When stressed, those animals had above-average levels of free-floating stress hormones and were more stressed (Champagne et al., 2003; Champagne & Mashoodh, 2009).

Epigenetics provides a mechanism by which the effects of childhood trauma, poverty, or malnutrition may last a lifetime (Nugent et al., 2016; Peter et al., 2016; Swartz et al., 2016). Our life events can mark us at the deepest level. Child abuse may leave its fingerprints in a person's genome. Moreover, it now appears that some epigenetic changes are passed down to future generations. In one experiment, mice whose grandparents learned to associate the smell of orange blossoms with shock were themselves startled when first exposed to the scent (Dias & Ressler, 2014). Conceivably, your health and well-being could be affected by stresses or pollutants that your parent or even grandparent experienced (McCarrey, 2015; Skinner, 2014; Yehuda et al., 2016). In one study, Holocaust trauma survivors shared epigenetic alterations with their offspring (Yehuda et al., 2016).

Epigenetics research may solve some scientific mysteries, such as why only one member of an identical twin pair may develop a genetically influenced mental disorder (Spector, 2012). Epigenetics can also help explain why identical twins may look slightly different. Researchers studying mice have found that in utero exposure to certain chemicals can cause genetically identical twins to have different-colored fur (Dolinoy et al., 2007).

Lasting effects

Canadian Senator Murray Sinclair, seen here with Prime Minister Justin Trudeau, was honored for an in-depth report on the devastating effects of Canada's long running residential school program that removed Aboriginal Canadian children from their families. As psychologist Susan

Pinker (2015) observed, the epigenetic effects of forced family separation “can play out, not only in the survivors of residential schools but in subsequent generations.”

The threadlike structures made largely of DNA molecules are called _____.

A small segment of DNA that codes for particular proteins is referred to as a _____.

When the mother's egg and the father's sperm unite, each contributes

- a. one chromosome pair.
- b. 23 chromosomes.
- c. 23 chromosome pairs.
- d. 25,000 chromosomes.

Fraternal twins result when

- a. a single egg is fertilized by a single sperm and then splits.
- b. a single egg is fertilized by two sperm and then splits.
- c. two eggs are fertilized by two sperm.
- d. two eggs are fertilized by a single sperm.

_____ twins share the same DNA.

Adoption studies seek to understand genetic influences on personality. They do this mainly by

- a. comparing adopted children with nonadopted children.
- b. evaluating whether adopted children's personalities more closely resemble those of their adoptive parents or their biological parents.
- c. studying the effect of prior neglect on adopted children.
- d. studying the effect of children's age at adoption.

From the very first weeks of life, infants differ in their characteristic emotional reactions, with some infants being intense and anxious, while others are easygoing and relaxed. These differences are usually explained as differences in _____.

_____ is the proportion of variation among individuals in groups that we can attribute to genes.

Epigenetics is the study of the molecular mechanisms by which _____ trigger or block genetic expression.

Evolutionary Psychology: Understanding Human Nature

LOQ 4-6 How do evolutionary psychologists use natural selection to explain behavior tendencies?

Behavior geneticists explore the genetic and environmental roots of human differences. [Evolutionary psychologists](#) instead focus mostly on what makes us so much alike as humans. They use Charles Darwin's principle of [natural selection](#)—"arguably the most momentous idea ever to occur to a human mind," said Richard Dawkins (2007)—to understand the roots of behavior and mental processes. The idea, simplified, is this:

evolutionary psychology the study of the evolution of behavior and the mind, using principles of natural selection.

natural selection the principle that inherited traits that better enable an organism to survive and reproduce in a particular environment will (in competition with other trait variations) most likely be passed on to succeeding generations.

- Organisms' varied offspring compete for survival.
- Certain biological and behavioral variations increase organisms' reproductive and survival chances in their particular environment.
- Offspring that survive are more likely to pass their genes to ensuing generations.
- Thus, over time, population characteristics may change.

To see these principles at work, let's consider a straightforward example in foxes.

Natural Selection and Adaptation

A fox is a wild and wary animal. If you capture a fox and try to befriend it, be careful: If the timid fox cannot flee, it may snack on your fingers. Russian scientist Dmitry Belyaev wondered how our human ancestors had domesticated dogs from their equally wild wolf forebears. Might he, within a comparatively short stretch of time, accomplish a similar feat by transforming the fearful fox into a friendly fox?

Eric Isselee/
Shutterstock

To find out, Belyaev set to work with 30 male and 100 female foxes. From their offspring he selected and mated the tamest 5 percent of males and 20 percent of females. (He measured tameness by the foxes' responses to attempts to feed, handle, and stroke them.) Over more than 30 generations of foxes, Belyaev and his successor, Lyudmila Trut, repeated that simple procedure. Forty years and 45,000 foxes later, they had a new breed of foxes that, in Trut's (1999) words, were "docile, eager to please, and unmistakably domesticated. . . . Before our eyes, 'the Beast' has turned into 'beauty,' as the aggressive behavior of our herd's wild [ancestors] entirely disappeared." So friendly and eager for human contact were these animals, so inclined to whimper to attract attention and to lick people like affectionate dogs, that the cash-strapped institute seized on a way to raise funds—marketing its friendly foxes as house pets.

Over time, traits that give an individual or a species a reproductive advantage are *selected* and will prevail. Animal-breeding experiments manipulate genetic selection. Dog breeders have given us sheepdogs that herd, retrievers that retrieve, trackers that track, and pointers that point (Plomin et al., 1997). Psychologists, too, have bred animals to be serene or reactive, quick learners or slow ones.

Does the same process work with naturally occurring selection? Does natural selection explain our human tendencies? Nature has indeed selected advantageous variations from the new gene combinations produced at each human conception plus the **mutations** (random errors in gene replication) that sometimes result. But the tight genetic leash that predisposes a dog's retrieving, a cat's pouncing, or a bird's nesting is looser on humans. The genes selected during our ancestral history provide more than a long leash; they give us a great capacity to learn and therefore to *adapt* to life in varied environments, from the tundra to the jungle. Genes and experience together wire the brain. Our adaptive flexibility in responding to different environments contributes to our *fitness*—our ability to survive and reproduce.

mutation a random error in gene replication that leads to a change.

RETRIEVAL PRACTICE

RP-5 How are Belyaev and Trut's breeding practices similar to, and how do they differ from, the way natural selection normally occurs?

ANSWER: Over multiple generations, Belyaev and Trut selected and bred foxes that exhibited a trait they desired: tameness. This process is similar to naturally occurring selection, but it differs in that natural selection is much slower, and normally favors traits (including those arising from mutations) that contribute to reproduction and survival.

Evolutionary Success Helps Explain Similarities

Human differences grab our attention. Guinness World Records entertain us with the tallest, oldest, hairiest, and most-tattooed humans. But our deep similarities also demand explanation. At the Amsterdam Airport's international arrivals area, one sees the same delighted joy on the faces of Indonesian grandmothers, Chinese children, and homecoming Dutch.

Evolutionary psychologist Steven Pinker (2002, [p. 73](#)) noted that, thanks to human evolution, our shared human traits—our emotions, drives, and reasoning—“have a common logic across cultures.”

Our Genetic Legacy

Our similarities arise from our shared human *genome*, our common genetic profile. No more than 5 percent of the genetic differences among humans arise from population group differences. Some 95 percent of genetic variation exists *within* populations (Rosenberg et al., 2002). The typical genetic difference between two Icelandic villagers or between two Kenyans is much greater than the *average* difference between the two groups. Thus, if after a worldwide catastrophe only Icelanders or Kenyans survived, the human species would suffer only “a trivial reduction” in its genetic diversity (Lewontin, 1982).

And how did we develop this shared human genome? At the dawn of human history, our ancestors faced certain questions: Who is my ally, who is my foe? With whom should I mate? What food should I eat? Some individuals answered those questions more successfully than others. For example, women who experienced nausea in the critical first three months of pregnancy were genetically predisposed to avoid certain bitter, strongly flavored, and novel foods. Avoiding such foods had survival value, since they are the very foods most often toxic to prenatal development (Profet, 1992; Schmitt & Pilcher, 2004). Early humans disposed to eat nourishing rather than poisonous foods survived to contribute their genes to later generations. Those who deemed leopards “nice to pet” often did not.

Similarly successful were those whose mating helped them produce and nurture offspring. Over generations, the genes of individuals not disposed to mate or nurture tended to be lost from the human gene pool. As success-enhancing genes continued to be selected, behavioral tendencies and learning capacities emerged that prepared our Stone Age ancestors to survive, reproduce, and send their genes into the future, and into you.

Across our cultural differences, we even share a “universal moral grammar” (Mikhail, 2007). Men and women, young and old, liberal and conservative, living in Sydney or Seoul, all respond negatively when asked, “If a lethal gas is leaking into a vent and is headed toward a room with seven

people, is it okay to push someone into the vent—saving the seven but killing the one?” And they all respond more approvingly when asked if it’s okay to *allow* someone to fall into the vent, again sacrificing one life but saving seven. Our shared moral instincts survive from a distant past where we lived in small groups in which direct harm-doing was punished. For all such universal human tendencies, from our intense need to give parental care to our shared fears and lusts, evolutionary theory proposes a one-stop-shopping explanation (Schloss, 2009).

Despite high infant mortality and rampant disease in past millennia, not one of your countless ancestors died childless.

As inheritors of this prehistoric legacy, we are genetically predisposed to behave in ways that promoted our ancestors’ surviving and reproducing. But in some ways, we are biologically prepared for a world that no longer exists. We love the taste of sweets and fats, nutrients that prepared our physically active ancestors to survive food shortages. But few of us now hunt and gather our food; instead, we find sweets and fats in fast-food outlets and vending machines. Our natural dispositions, rooted deep in history, are mismatched with today’s junk-food and often inactive lifestyle.

Those who are troubled by an apparent conflict between scientific and religious accounts of human origins may find it helpful to consider that different perspectives of life can be complementary. For example, the scientific account attempts to tell us *when* and *how*; religious creation stories usually aim to tell about an ultimate *who* and *why*. As Galileo explained to the Grand Duchess Christina, “The Bible teaches how to go to heaven, not how the heavens go.”

Evolutionary Psychology Today

Darwin’s theory of evolution has become one of biology’s fundamental organizing principles and lives on in the *second Darwinian revolution*: the application of evolutionary principles to psychology. In concluding *On the*

Origin of Species, Darwin (1859, [p. 346](#)) anticipated this, foreseeing “open fields for far more important researches. Psychology will be based on a new foundation.”

Elsewhere in this text, we address questions that intrigue evolutionary psychologists: Why do infants start to fear strangers about the time they become mobile? Why do so many more people have phobias about spiders, snakes, and heights than about more dangerous threats, such as guns and electricity? And why do we fear safe air travel so much more than dangerous driving?

To see how evolutionary psychologists think and reason, let’s pause to explore their answers to two questions: How are males and females alike? How and why does their sexuality differ?

For an interactive tutorial on evolutionary psychology concepts, visit **Concept Practice: Evolutionary Explanations**.

An Evolutionary Explanation of Human Sexuality

LOQ 4-7 How might an evolutionary psychologist explain male-female differences in sexuality and mating preferences?

Having faced many similar challenges throughout history, males and females have adapted in similar ways: We eat the same foods, avoid the same dangers, and perceive, learn, and remember similarly. It is only in those domains where we have faced differing adaptive challenges—most obviously in behaviors related to reproduction—that we differ, say evolutionary psychologists.

Jacob Hamblin/
Shutterstock

Male-Female Differences in Sexuality

And differ we do. Consider sex drives. Both men and women are sexually motivated, some women more so than many men. Yet, on average, who thinks more about sex? Masturbates more often? Initiates more sex? Views more pornography? The answers worldwide: *men, men, men, and men* (Baumeister et al., 2001; Lippa, 2009; Petersen & Hyde, 2010). No surprise, then, that in one BBC survey of more than 200,000 people in 53 nations, men everywhere more strongly agreed that “I have a strong sex drive” and “It doesn’t take much to get me sexually excited” (Lippa, 2008).

Indeed, “with few exceptions anywhere in the world,” reported cross-cultural psychologist Marshall Segall and his colleagues (1990, [p. 244](#)), “males are more likely than females to initiate sexual activity.” This is the largest sexuality difference between males and females, but there are others (Hyde, 2005; Petersen & Hyde, 2010; Regan & Atkins, 2007). To see if you can predict some of these differences in Americans, take the quiz in [TABLE 4.1](#).

TABLE 4.1

Predict the Responses

Researchers asked samples of U.S. adults whether they agreed or disagreed with the following statements. For each item, give your best guess about the percentage who agreed with the statement.

Statement ²	Percentage of males who agreed	Percentage of females who agreed
1. If two people really like each other, it's all right for them to have sex even if they've known each other for a very short time	_____	_____

Item	Gay men	Lesbian women
2. I can imagine myself being comfortable and enjoying “casual” sex with different partners.	_____	_____
3. Affection was the reason I first had intercourse.	_____	_____
4. I think about sex every day, or several times a day.	_____	_____
5. Pornography is “morally acceptable.”	_____	_____

Information from Bailey et al., 2000; Dugan, 2015; Laumann et al., 1994; Pryor et al., 2005.

Heterosexual men are alert for women’s interest, and often misperceive a woman’s friendliness as a sexual come-on (Abbey, 1987). In one speed-dating study, men believed their dating partners expressed more sexual interest than the partners reported actually expressing (Perilloux et al., 2012). This *sexual overperception bias* is strongest among men who require little emotional closeness before intercourse (Howell et al., 2012; Perilloux et al., 2012).

Many gender similarities and differences transcend sexual orientation. Compared with lesbians, gay men (like straight men) report more responsiveness to visual sexual stimuli, and more concern with their partner’s physical attractiveness (Bailey et al., 1994; Doyle, 2005; Schmitt, 2007; Sprecher et al., 2013). Gay male couples also report having sex more often than do lesbian couples (Peplau & Fingerhut, 2007). And (also like straight

men) gay men report more interest in uncommitted sex.

Webster, G. D., Jonason, P. K., & Schember, T. O. (2009). Hot topics and popular papers in evolutionary psychology: Analyses of title words and citation counts in *Evolution and Human Behavior*, 1979–2008. *Evolutionary Psychology*, 7, 348–362.

What evolutionary psychologists study

Each word's size in this word cloud shows how frequently it has appeared in evolutionary psychology article titles. (Information from Gregory Webster, Peter Jonason, and Tatiana Schember [2009] from all articles published in *Evolution and Human Behavior* between 1997 and 2008.)

“It’s not that gay men are oversexed; they are simply men whose male desires bounce off other male desires rather than off female desires.”

Steven Pinker, *How the Mind Works*, 1997

Natural Selection and Mating Preferences

Natural selection is nature selecting traits and appetites that contribute to survival and reproduction. Evolutionary psychologists use this principle to explain how men and women differ more in the bedroom than in the boardroom. Our natural yearnings, they say, are our genes' way of reproducing themselves. "Humans are living fossils—collections of mechanisms produced by prior selection pressures" (Buss, 1995).

The New Yorker
Collection, 2010,
Ariel Molvig, from
cartoonbank.com.
All Rights Reserved.

Why do women tend to be choosier than men when selecting sexual partners? Women have more at stake. To send her genes into the future, a woman must—at a minimum—conceive and protect a fetus growing inside her body for up to nine months. No surprise then, that heterosexual women prefer partners who will offer their joint offspring support and protection: stick-around dads over likely cads. Heterosexual women are attracted to tall men with slim waists and broad shoulders—all signs of reproductive success (Mautz et al., 2013). And they prefer men who seem mature, dominant, bold, and affluent (Conroy-Beam et al., 2015; Fales et al., 2016; Lukaszewski et al., 2016). One study of hundreds of Welsh pedestrians asked people to rate a driver pictured at the wheel of a humble Ford Fiesta or a swanky Bentley. Men said a female driver was equally attractive in both cars. Women, however, found a male driver more attractive if he was in the luxury car (Dunn & Searle, 2010).

The data are in, say evolutionists: Men pair widely; women pair wisely. And what traits do straight men find desirable? Some, such as a woman's smooth skin and youthful shape, cross place and time, and they convey health and fertility (Buss, 1994). Mating with such women might increase a man's chances of sending his genes into the future. And sure enough, men feel most attracted to women whose waist is roughly a third narrower than their hips—a sign of future fertility (Lewis et al., 2015; Perilloux et al., 2010). Even blind men show this preference for women with a low waist-to-hip ratio (Karremans et al., 2010). Men are most attracted to women whose ages in the ancestral past (when ovulation began later than today) would be associated with peak fertility (Kenrick et al., 2009). Thus, teen boys are most excited by a woman several years older than themselves, mid-twenties men prefer women around their own age, and older men prefer younger women. This

pattern consistently appears across European singles ads, Indian marital ads, and marriage records from North and South America, Africa, and the Philippines (Singh, 1993; Singh & Randall, 2007).

MGP/Photodisc/Getty Images

There is a principle at work here, say evolutionary psychologists: Nature selects behaviors that increase genetic success. As mobile gene machines, we are designed to prefer whatever worked for our ancestors in their environments. They were genetically predisposed to act in ways that would produce children, grandchildren, and beyond. Had they not been, we wouldn't be here. As carriers of their genetic legacy, we are similarly predisposed.

To experience a demonstration and explanation of evolutionary psychology and mating preferences, visit **PsychSim 6: Dating and Mating**.

Critiquing the Evolutionary Perspective

LOQ 4-8 What are the key criticisms of evolutionary explanations of human sexuality, and how do evolutionary psychologists respond?

Most psychologists agree that natural selection prepares us for survival and

reproduction. But critics say there is a weakness in evolutionary psychology's explanation of our mating preferences. Let's consider how an evolutionary psychologist might explain the findings in a startling study (Clark & Hatfield, 1989), and how a critic might object.

In this experiment, someone posing as a stranger approached people of the other sex and remarked, "I have been noticing you around campus. I find you to be very attractive." The "stranger" then asked a question, which was sometimes "Would you go to bed with me tonight?" What percentage of men and women do you think agreed? An evolutionary explanation of sexuality would predict that women would be choosier than men in selecting their sexual partners. In fact, not a single woman agreed—but 70 percent of the men did. A repeat of this study in France produced a similar result (Guéguen, 2011). The research seemed to support an evolutionary explanation.

Or did it? Critics note that evolutionary psychologists start with an effect—in this case, the survey result showing that men were more likely to accept casual sex offers—and work backward to explain what happened. What if research showed the opposite effect? If men refused an offer for casual sex, might we not reason that men who partner with one woman for life make better fathers, whose children more often survive?

Other critics ask why we should try to explain today's behavior based on decisions our distant ancestors made thousands of years ago. Don't cultural expectations also bend the genders? Alice Eagly and Wendy Wood (1999; Eagly, 2009) point to the smaller behavioral differences between men and women in cultures with greater gender equality. Such critics believe that *social learning theory* offers a better, more immediate explanation for these results. We all learn [social scripts](#)—our culture's guide to how people should act in certain situations. By watching and imitating others in their culture, women may learn that sexual encounters with strangers can be dangerous, and that casual sex may not offer much sexual pleasure (Conley, 2011). This alternative explanation of the study's effects proposes that women react to sexual encounters in ways that their modern culture teaches them. And men's reactions may reflect their learned social scripts: "Real men" take advantage of every opportunity to have sex.

social script a culturally modeled guide for how to act in various situations.

A third criticism focuses on the social consequences of accepting an evolutionary explanation. Are heterosexual men truly hardwired to have sex with any woman who approaches them? If so, does it mean that men have no moral responsibility to remain faithful to their partners? Does this explanation excuse men's sexual aggression—"boys will be boys"—because of our evolutionary history?

"It is dangerous to show a man too clearly how much he resembles the beast, without at the same time showing him his greatness. It is also dangerous to allow him too clear a vision of his greatness without his baseness. It is even more dangerous to leave him in ignorance of both."

Blaise Pascal, *Pensées*, 1659

Evolutionary psychologists agree that much of who we are is *not* hardwired. "Evolution forcefully rejects a genetic determinism," insisted one research team (Confer et al., 2010). Genes are not destiny. And evolutionary psychologists remind us that men and women, having faced similar adaptive problems, are far more alike than different. Natural selection has prepared us to be flexible. We humans have a great capacity for learning and social progress. We adjust and respond to varied environments. We adapt and survive, whether we live in the Arctic or the desert.

Evolutionary psychologists also agree with their critics that some traits and behaviors, such as suicide, are hard to explain in terms of natural selection (Barash, 2012; Confer et al., 2010). But they ask us to remember evolutionary psychology's scientific goal: to explain behaviors and mental traits by offering testable predictions using principles of natural selection. We may, for example, predict that people are more likely to perform favors for those who share their genes or can later return those favors. Is this true? (The answer is *Yes*.) And evolutionary psychologists remind us that studying how we *came to be* need not dictate how we *ought to be*. Understanding our tendencies can help us overcome them.

RETRIEVAL PRACTICE

RP-6 How do evolutionary psychologists explain male-female

differences in sexuality?

ANSWER: Evolutionary psychologists theorize that females have inherited their ancestors' tendencies to be more cautious sexually because of the challenges associated with incubating and nurturing offspring. Males have inherited a tendency to be more casual about sex, because their act of fathering requires a smaller investment.

RP-7 What are the three main criticisms of the evolutionary explanation of human sexuality?

ANSWER: (1) It starts with an effect and works backward to propose an explanation. (2) This explanation may overlook the effects of cultural expectations and socialization. (3) Men could use such explanations to rationalize irresponsible behavior toward women.

Culture, Gender, and Other Environmental Influences

From conception onward, we are the product of a cascade of *interactions* between our genetic predispositions and our surrounding environments (McGue, 2010). Our genes affect how people react to and influence us. Forget nature *versus* nurture; think nature *via* nurture.

Imagine two babies, one genetically predisposed to be attractive, sociable, and easygoing, the other less so. Assume further that the first baby attracts more affectionate and stimulating care and so develops into a warmer and more outgoing person. As the two children grow older, the more naturally outgoing child may seek more activities and friends that encourage further social confidence.

What has caused their resulting personality differences? Neither heredity nor experience acts alone. Environments trigger gene activity. And our genetically influenced traits *evoke* significant responses in others. Thus, a child's impulsivity and aggression may evoke an angry response from a parent or teacher, who reacts warmly to well-behaved children in the family or classroom. In such cases, the child's nature and the parents' nurture interact. Gene and scene dance together.

Identical twins not only share the same genetic predispositions, they also seek and create similar experiences that express their shared genes (Kandler et al., 2012). This helps explain why identical twins raised in different families have recalled their parents' warmth as remarkably similar—almost as similar as if they had been raised by the same parents (Plomin et al., 1988, 1991, 1994). Fraternal twins have more differing recollections of their early family life—even if raised in the same family! “Children experience us as different parents, depending on their own qualities,” noted Sandra Scarr (1990).

How Does Experience Influence Development?

Our genes, when expressed in specific environments, influence our

developmental differences. We are like coloring books, with certain lines predisposed and experience filling in the full picture. We are formed by nature and nurture, but what are the most influential components of our nurture? How do our early experiences, our family and peer relationships, and all our other experiences guide our development and contribute to our diversity?

The formative nurture that conspires with nature begins at conception, with the prenatal environment in the womb, where embryos receive differing nutrition and varying levels of exposure to toxic agents. Nurture then continues outside the womb, where our early experiences foster brain development.

Experience and Brain Development

LOQ 4-9 How do early experiences modify the brain?

Developing neural connections prepare our brain for thought, language, and other later experiences. So how do early experiences leave their fingerprints in the brain? Mark Rosenzweig, David Krech, and their colleagues (1962) opened a window on that process when they raised some young rats in solitary confinement and others in a communal playground. When they later analyzed the rats' brains, those who died with the most toys had won. The rats living in the enriched environment, which simulated a natural environment, usually developed a heavier and thicker brain cortex ([FIGURE 4.4](#)).

FIGURE 4.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 4.4 Experience affects brain development

Mark Rosenzweig, David Krech, and their colleagues (1962) raised rats either alone in an environment without playthings, or with other rats in an environment enriched with playthings that changed daily. In 14 of 16

repetitions of this basic experiment, rats in the enriched environment developed significantly more cerebral cortex (relative to the rest of the brain's tissue) than did those in the impoverished environment.

Rosenzweig was so surprised that he repeated the experiment several times before publishing his findings (Renner & Rosenzweig, 1987; Rosenzweig, 1984). So great are the effects that, shown brief video clips of rats, you could tell from their activity and curiosity whether their environment had been impoverished or enriched (Renner & Renner, 1993). After 60 days in the enriched environment, the rats' brain weights increased 7 to 10 percent and the number of *synapses* mushroomed by about 20 percent (Kolb & Whishaw, 1998). The enriched environment literally increased brain power.

Such results have motivated improvements in environments for laboratory, farm, and zoo animals—and for children in institutions. Stimulation by touch or massage also benefits infant rats and premature babies (Field et al., 2007; Sarro et al., 2014). “Handled” infants of both species develop faster neurologically and gain weight more rapidly. Premies who have had skin-to-skin contact with their mothers sleep better, experience less stress, and show better cognitive development 10 years later (Feldman et al., 2014).

Nature and nurture interact to sculpt our synapses. Brain maturation provides us with an abundance of neural connections. Experience—sights and smells, touches and tastes, music and movement—activates and strengthens some neural pathways while others weaken from disuse. Similar to paths through a forest, less-traveled neural pathways gradually disappear and popular ones are broadened (Gopnik et al., 2015). By puberty, this *pruning process* results in a massive loss of unemployed connections.

Courtesy of C. Brune

Stringing the circuits young

String musicians who started playing before age 12 have larger and more complex neural circuits controlling the note-making left-hand fingers than do string musicians whose training started later (Elbert et al., 1995).

Here at the juncture of nurture and nature is the biological reality of early childhood learning. During early childhood—while excess connections are still on call—youngsters can most easily master such skills as the grammar and accent of another language. Lacking any exposure to language before adolescence, a person will never master any language. Likewise, lacking visual experience during the early years, a person whose vision is later restored by cataract removal will never achieve normal perceptions (Gregory, 1978; Wiesel, 1982). Without that early visual stimulation, the brain cells normally assigned to vision will die or be diverted to other uses. The maturing brain's rule: Use it or lose it.

Although normal stimulation during the early years is critical, the brain's development does not end with childhood. Thanks to the brain's amazing *plasticity*, our neural tissue is ever changing and reorganizing in response to new experiences. New neurons are also born. If a monkey pushes a lever with the same finger many times a day, brain tissue controlling that finger will change to reflect the experience ([FIGURE 4.5](#)). Human brains work similarly. Whether learning to keyboard, skateboard, or navigate London's streets, we perform with increasing skill as our brain incorporates the learning (Ambrose, 2010; Maguire et al., 2000).

How Much Credit or Blame Do Parents Deserve?

LOQ 4-10 In what ways do parents and peers shape children's development?

In procreation, a woman and a man shuffle their gene decks and deal a life-forming hand to their child-to-be, who is then subjected to countless influences beyond their control. Parents, nonetheless, feel enormous satisfaction in their children's successes or guilt and shame over their failures. They beam over the child who wins trophies and titles. They wonder where they went wrong with the child who is repeatedly in trouble.

"To be frank, officer, my parents never set boundaries."

The New Yorker Collection, 2007, Julia Suits
from cartoonbank.com. All Rights Reserved.

Freudian psychiatry and psychology encouraged such ideas by blaming problems from asthma to schizophrenia on “bad mothering.” Believing that parents shape their offspring as a potter molds clay, many people praise parents for their children’s virtues and blame them for their children’s vices, and for the psychological harm that toxic parents presumably inflict on their fragile children. No wonder having and raising children can seem so risky.

But do parents really produce wounded future adults by being (take your pick from the toxic-parenting lists) overbearing—or uninvolved? Pushy—or indecisive? Overprotective—or distant? Should we then blame our parents for our failings, and ourselves for our children’s failings? Or does talk of wounding fragile children through normal parental mistakes trivialize the brutality of real abuse?

"So I blame you for everything—whose fault is that?"

The New Yorker Collection, 2001,
Barbara Smaller from cartoonbank.com.
All Rights Reserved.

Parents do matter. But parenting wields its largest effects at the extremes: the abused children who become abusive, the deeply loved but firmly handled who become self-confident and socially competent. The power of the family environment also appears in the remarkable academic and vocational successes of many children of people who leave their home countries, such as those of refugees who fled war-torn Vietnam and Cambodia—successes attributed to close knit, supportive, even demanding families (Caplan et al., 1992). Asian-Americans and European-Americans often differ in their parenting expectations. An Asian-American mother may push her children to do well, but usually not in a way that strains their relationship (Fu & Markus, 2014). Having a supportive “Tiger Mother”—one who pushes her children and works alongside them—tends to motivate children to work harder. European-Americans, however, might see this as pushy parenting that undermines children’s motivation (Deal, 2011).

Yet in personality measures, shared environmental influences from the womb onward typically account for less than 10 percent of children’s differences. In the words of behavior geneticists Robert Plomin and Denise Daniels (1987; Plomin, 2011), “Two children in the same family are [apart from their shared genes] as different from one another as are pairs of children selected randomly from the population.” To developmental psychologist Sandra Scarr (1993), this implied that “parents should be given less credit for

kids who turn out great and blamed less for kids who don't." So, knowing that children's personalities are not easily sculpted by parental nurture, perhaps parents can relax and love their children for who they are.

Lorenzo Ciniglio/Polaris

A controlling mom

Amy Chua, law professor and author of *Battle Hymn of the Tiger Mother* (2011), sparked controversy by comparing strict "Chinese" and more permissive "Western" parenting styles. In raising her two daughters, Chua came to appreciate the benefits and the costs of the more externally controlled traditional Chinese parenting.

Peer Influence

As children mature, what other experiences do the work of nurturing? At all ages, but especially during childhood and adolescence, we seek to fit in with our groups (Harris, 1998, 2000):

- Preschoolers who disdain a certain food often will eat that food if put at a table with a group of children who like it.
- Children who hear English spoken with one accent at home and another in the neighborhood and at school will invariably adopt the accent of their peers, not their parents. Accents (and slang) reflect culture, "and children get their culture from their peers," as Judith Rich Harris (2007) has noted.

“Men resemble the times more than they resemble their fathers.”

Ancient Arab proverb

- Teens who start smoking typically have friends who model smoking, suggest its pleasures, and offer cigarettes (J. S. Rose et al., 1999; R. J. Rose et al., 2003). Part of this peer similarity may result from a *selection effect*, as kids seek out peers with similar attitudes and interests. Those who smoke (or don't) may select as friends those who also smoke (or don't).

The power to select a child's neighborhood and schools gives some parents the ability to influence the culture that shapes the child's peer group. And because neighborhood influences matter, parents may want to become involved in intervention programs that aim at a whole school or neighborhood. If the vapors of a toxic climate are seeping into a child's life, that climate—not just the child—needs reforming. Even so, peers are but one medium of cultural influence. As an African proverb declares, “It takes a village to raise a child.”

RETRIEVAL PRACTICE

RP-8 What is the *selection effect*, and how might it affect a teen's decision to join sports teams at school?

ANSWER: Adolescents tend to *select* similar others and to sort themselves into like-minded groups. For an athletic teen, this could lead to finding other athletic teens and joining school teams together.

Allan Shoemake/Stockbyte/

Peer power

As we develop, we play, mate, and partner with peers. No wonder children and youths are so sensitive and responsive to peer influences.

Cultural Influences

LOQ 4-11 How does culture affect our behavior?

Compared with the narrow path taken by flies, fish, and foxes, the road along which environment drives us is wider. The mark of our species—nature's great gift to us—is our ability to learn and adapt. We come equipped with a huge cerebral hard drive ready to receive cultural software.

Culture is the behaviors, ideas, attitudes, values, and traditions shared by a group of people and transmitted from one generation to the next (Brislin, 1988; Cohen, 2009). Human nature, noted Roy Baumeister (2005), seems designed for culture. We are social animals, but more. Wolves are social animals; they live and hunt in packs. Ants are incessantly social, never alone. But “culture is a better way of being social,” observed Baumeister. Wolves function pretty much as they did 10,000 years ago. We enjoy countless things that were unknown to our century-ago ancestors. Culture works.

culture the enduring behaviors, ideas, attitudes, values, and traditions shared by a group of people and transmitted from one generation to the next.

Other animals exhibit smaller kernels of culture. Chimpanzees sometimes invent customs—using leaves to clean their bodies, slapping branches to get attention, and doing a “rain dance” by slowly displaying themselves at the start of rain—and pass them on to their peers and offspring (Whiten et al., 1999). Culture supports survival and reproduction by transmitting learned behaviors that give a group an edge. But human culture does more.

Thanks to our culture’s mastery of language, we humans enjoy the *preservation of innovation*. Within the span of this day, we have used Google, smart phones, digital hearing technology [DM], and a GPS running watch [ND]. On a grander scale, we have culture’s accumulated knowledge to thank for the last century’s 30-year extension of the average human life expectancy (in most countries where this book is being read). Moreover, culture enables an efficient *division of labor*. Although two lucky people get their name on this book (which transmits accumulated cultural wisdom), the product actually results from the coordination and commitment of a team of gifted people, no one of whom could produce it alone.

Across cultures, we differ. But beneath differences is our great similarity—our capacity for culture. Culture transmits the customs and beliefs that enable us to communicate, to exchange money for things, to play, to eat, and to drive with agreed-upon rules and without crashing into one another.

Variation Across Cultures

We see our adaptability in cultural variations among our beliefs and our values, in how we nurture our children and bury our dead, and in what we wear (or whether we wear anything at all). We are ever mindful that the worldwide readers of this book are culturally diverse. You and your ancestors reach from Australia to Africa and from Singapore to Sweden.

Riding along with a unified culture is like biking with the wind: As it carries us along, we hardly notice it is there. When we try biking *against* the wind we feel its force. Face-to-face with a different culture, we become aware of the cultural winds. Visiting Europe, most North Americans notice the smaller cars, the left-handed use of the fork, the uninhibited attire on the beaches. Stationed in Iraq, Afghanistan, and Kuwait, American and European soldiers alike realized how liberal their home cultures were. Arriving in North America, visitors from Japan and India struggle to understand why so many

people wear their dirty street shoes in the house.

But humans in varied cultures nevertheless share some basic moral ideas. Even before they can walk, babies prefer helpful people over naughty ones (Hamlin et al., 2011). Worldwide, people prize honesty, fairness, and kindness (McGrath, 2015). Yet each cultural group also evolves its own **norms**—rules for accepted and expected behavior. The British have a norm for orderly waiting in line. Many South Asians use only the right hand for eating. Sometimes social expectations seem oppressive: “Why should it matter how I dress?” Yet, norms—how to greet, how to eat—grease the social machinery.

norm an understood rule for accepted and expected behavior. Norms prescribe “proper” behavior.

When cultures collide, their differing norms often befuddle. Should we greet people by shaking hands, bowing, or kissing each cheek? Knowing what sorts of gestures and compliments are culturally appropriate, we can relax and enjoy one another without fear of embarrassment or insult.

When we don’t understand what’s expected or accepted, we may experience *culture shock*. People from Mediterranean cultures have perceived northern Europeans as efficient but cold and preoccupied with punctuality (Triandis, 1981). People from time-conscious Japan—where bank clocks keep exact time, pedestrians walk briskly, and postal clerks fill requests speedily—have found themselves growing impatient when visiting Indonesia, where the pace of life is more leisurely (Levine & Norenzayan, 1999). Someone from the European community, which requires 20 paid vacation days each year, may also experience culture shock when working in the United States, which does not guarantee workers any paid vacation (Ray et al., 2013).

Variation Over Time

Like biological creatures, cultures vary and compete for resources, and thus evolve over time (Mesoudi, 2009). Consider how rapidly cultures may change. English poet Geoffrey Chaucer (1342–1400) is separated from a modern Briton by only 25 generations, but the two would have great difficulty communicating. At the beginning of the last century, your ancestors lived in a world without cars, radio broadcasting, or widespread electric power and light. In the thin slice of history since 1960, most Western cultures have changed with astonishing speed. Middle-class people enjoy the convenience of air-conditioned housing, online shopping, anywhere-anytime

electronic communication, and—enriched by doubled per-person real income—eating out more than twice as often as did their grandparents back in the culture of 1960. Many people now enjoy expanded human rights. And with greater economic independence, today’s women more often marry for love and less often endure abusive relationships.

But some changes seem not so wonderfully positive. Had you fallen asleep in the United States in 1960 and awakened today, you would open your eyes to a culture with more depression and more economic inequality. You would also find North Americans—like their counterparts in Britain, Australia, and New Zealand—spending more hours at work, fewer hours with friends and family, and fewer hours asleep (BLS, 2011; Putnam, 2000).

Whether we love or loathe these changes, we cannot fail to be impressed by their breathtaking speed. And we cannot explain them by changes in the human gene pool, which evolves far too slowly to account for high-speed cultural transformations. Cultures vary. Cultures change. And cultures shape our lives.

Culture and the Self

LOQ 4-12 How do individualist and collectivist cultures differ in their values and goals?

Imagine that someone ripped away your social connections, making you a solitary refugee in a foreign land. How much of your identity would remain intact?

If you are an **individualist**, a great deal. You would have an independent sense of “me,” and an awareness of your unique personal convictions and values. Individualists prioritize personal goals. They define their identity mostly in terms of personal traits. They strive for personal control and individual achievement.

individualism giving priority to one’s own goals over group goals and defining one’s identity in terms of personal attributes rather than group identifications.

Kyodo/Reuters/Newscom

Considerate collectivists

Japan's collectivist values, including duty to others and social harmony, were on display after the devastating 2011 earthquake and tsunami. Virtually no looting was reported, and residents remained calm and orderly, as shown here while waiting for drinking water.

Individualists do share the human need to belong. They join groups. But they are less focused on group harmony and doing their duty to the group (Brewer & Chen, 2007). Being more self-contained, individualists move in and out of social groups more easily. They feel relatively free to switch places of worship, change jobs, or even leave their extended families and migrate to a new place. Marriage is often for as long as they both shall love.

If set adrift in a foreign land as a [collectivist](#), you might experience a greater loss of identity. Cut off from family, groups, and loyal friends, you would lose the connections that have defined who you are. *Group identifications* provide a sense of belonging, a set of values, and an assurance of security. Collectivists have deep attachments to their groups—their family, clan, or company. Elders receive respect. For example, the Law of the People's Republic of China on Protection of the Rights and Interests of the Elderly states that parents aged 60 or above can sue their sons and daughters if they fail to provide “for the elderly, taking care of them and comforting them, and cater[ing] to their special needs.”

collectivism giving priority to the goals of one's group (often one's extended family or work group) and defining one's identity accordingly.

Collectivists are like athletes who take more pleasure in their team's victory than in their own performance. They find satisfaction in advancing their groups' interests, even at the expense of personal needs. They preserve group spirit by avoiding direct confrontation, blunt honesty, and uncomfortable topics. They value humility, not self-importance (Bond et al., 2012). Instead of dominating conversations, collectivists hold back and display shyness when meeting strangers (Cheek & Melchior, 1990). Given the priority on "we," not "me," that individualized North American latte might sound selfishly demanding in Seoul (Kim & Markus, 1999).

A question: What do you think of people who willingly change their behavior to suit different people and situations? People in individualist countries (the United States and Brazil), typically describe them as "dishonest," "untrustworthy," and "insincere" (Levine, 2016). In traditionally collectivist countries (China, India, and Nepal), people more often describe them as "mature," "honest," "trustworthy," and "sincere."

"One needs to cultivate the spirit of sacrificing the *little me* to achieve the benefits of the *big me*."

Chinese saying

To explore your individualist versus collectivist self, engage online with **Assess Your Strengths: What Is Your Self Concept?**

To be sure, there is also diversity *within* cultures. Within many countries, there are also distinct subcultures related to one's religion, economic status, and region (Cohen, 2009). In China, greater collectivist thinking occurs in provinces that have produced rice, a difficult-to-grow crop that involves cooperation to sustain irrigation (Talhelm et al., 2014). In collectivist Japan, a spirit of individualism marks the "northern frontier" island of Hokkaido (Kitayama et al., 2006). And even in the most individualist countries, people have some collectivist values. But in general, people (especially men) in

competitive, individualist cultures have more personal freedom, are less geographically bound to their families, enjoy more privacy, and take more pride in personal achievements ([TABLE 4.2](#)).

TABLE 4.2

Value Contrasts Between Individualism and Collectivism

Concept	Individualism	Collectivism
<i>Self</i>	Independent (identity from individual traits)	Interdependent (identity from belonging to groups)
<i>Life task</i>	Discover and express one's uniqueness	Maintain connections, fit in, perform role
<i>What matters</i>	Me—personal achievement and fulfillment; rights and liberties; self-esteem	Us—group goals and solidarity; social responsibilities and relationships; family duty
<i>Coping method</i>	Change reality	Accommodate to reality
<i>Morality</i>	Defined by the individual (self-based)	Defined by social networks (duty-based)
<i>Relationships</i>	Many, often temporary or casual; confrontation acceptable	Few, close, and enduring; harmony is valued
<i>Attributing behavior</i>	Behavior reflects the individual's personality and attitudes	Behavior reflects social norms and roles

Information from Thomas Schoeneman (1994) and Harry Triandis (1994).

Individualists even prefer unusual names, as psychologist Jean Twenge noticed while seeking a name for her first child. When she and her colleagues (2010a, 2016a) analyzed the first names of 358 million American babies born between 1880 and 2015, they discovered that the most common baby names had become less common. As [FIGURE 4.6](#) illustrates, the percentage of boys and girls given one of the 10 most common names for their birth year has plunged. Collectivist Japan provides a contrast: Half of Japanese baby names are among the country's 10 most common names (Ogihara et al., 2015).

Data from Twenge et al., 2010a, 2016a.

FIGURE 4.6 A child like no other

Americans' individualist tendencies are reflected in their choice of names for their babies. In recent years, the percentage of American babies receiving one of that year's 10 most common names has plunged. (Data from Twenge et al., 2010a, 2016a.)

Cartoon by Buddy Hickerson

Information from Thomas Schoeneman (1994) and Harry Triandis (1994).

The individualist-collectivist divide appeared in reactions to medals

received during the 2000 and 2002 Olympic games. U.S. gold medal winners and the U.S. media covering them attributed the achievements mostly to the athletes themselves (Markus et al., 2006). “I think I just stayed focused,” explained swimming gold medalist Misty Hyman. “It was time to show the world what I could do.” Japan’s gold medalist in the women’s marathon, Naoko Takahashi, had a different explanation: “Here is the best coach in the world, the best manager in the world, and all of the people who support me—all of these things . . . became a gold medal.”

Individualists demand romance and personal fulfillment in marriage (Dion & Dion, 1993). In one survey, “keeping romance alive” was rated as important to a good marriage by 78 percent of U.S. women but only 29 percent of Japanese women (*American Enterprise*, 1992). In China, love songs have often expressed enduring commitment and friendship (Rothbaum & Tsang, 1998): “We will be together from now on. . . . I will never change from now to forever.”

Sam Harrel/Fairbanks/AK/U.S./ZUMA Press/Newscom

Collectivist culture

Although the United States is largely individualist, many cultural subgroups remain collectivist. This is true for many Alaska Natives, who demonstrate respect for tribal elders, and whose identity springs largely from their group affiliations.

As cultures evolve, some trends weaken and others grow stronger. Individualism and independence have been fostered by voluntary emigration, a capitalist economy, and a sparsely populated, challenging environment (Kitayama et al., 2009, 2010; Varnum et al., 2010). In Western cultures, individualism has increased strikingly over the last century, following closely

on the heels of increasing affluence (Grossmann & Varnum, 2015). This trend reached a new high in 2013 and 2014, when U.S. high school and college students reported increased tolerance, but also the greatest-ever interest in obtaining benefits for themselves and the lowest-ever willingness to donate to charity (Twenge, 2016; Twenge et al., 2012).

“I used to subscribe to *People*. Then I switched to *Us*. Now I just read *Self*.”

Lenny, quoted by Robert Levine, *Stranger in the Mirror: The Scientific Search for Self*, 2016

Culture and Child Raising

Child-raising practices reflect not only individual values, but also cultural values that vary across time and place. Should children be independent or obedient? If you live in a Westernized culture, you likely prefer independence. “You are responsible for yourself,” families and schools tell their children. “Follow your conscience. Be true to yourself. Discover your gifts.” Some Western parents go further, telling their children, “You are more special than other children” (Brummelman et al., 2015). (Not surprisingly, these children tend to have inflated self-views years later.) In the past, Western cultural values placed greater priority on obedience, respect, and sensitivity to others (Alwin, 1990; Remley, 1988). “Be true to your traditions,” parents then taught their children. “Be loyal to your heritage and country. Show respect toward your parents and other superiors.” Cultures change.

Stephen H. Reehl

Cultures vary

Parents everywhere care about their children, but raise and protect them differently depending on the surrounding culture. In big cities, parents keep children close. In smaller, close-knit communities, such as Scotland's Orkney Islands' town of Stromness, social trust has enabled parents to park their toddlers outside shops.

Children across place and time have thrived under various child-raising systems. Many North Americans now give children their own bedrooms and entrust them to day care. Upper-class British parents traditionally handed off routine caregiving to nannies, then sent their 10-year-olds away to boarding school. These children generally grew up to be pillars of British society.

Asians and Africans more often live in cultures that value emotional closeness. Infants and toddlers may sleep with their mothers and spend their days close to a family member (Morelli et al., 1992; Whiting & Edwards, 1988). These cultures encourage a strong sense of *family self*—a feeling that what shames the child shames the family, and what brings honor to the family brings honor to the self.

In traditional African Gusii society, babies nursed freely but spent most of the day on their mother's or siblings' back—with lots of body contact but little face-to-face and language interaction. In time, the toddler was weaned and handed over, often to an older sibling. What might appear as a lack of interaction to many Westerners might to these Gusii parents seem far

preferable to the lesser body contact experienced by babies pushed in strollers and left in playpens (Small, 1997). Such diversity in child raising cautions us against presuming that our culture's way is the only way to raise children successfully.

Developmental Similarities Across Groups

Mindful of how others differ from us, we often fail to notice the similarities predisposed by our shared biology. One 49-country study revealed smaller than expected nation-to-nation differences in personality traits, such as conscientiousness and extraversion (Terracciano et al., 2006). National stereotypes exaggerate differences that, although real, are modest: Australians see themselves as outgoing. German-speaking Swiss see themselves as conscientious. And Canadians see themselves as agreeable. Actually, compared with the person-to-person differences within groups, between-group differences are small. Regardless of our culture, we humans are more alike than different. We share the same life cycle. We speak to our infants in similar ways and respond similarly to their coos and cries (Bornstein et al., 1992a,b).

Even differences *within* a culture, such as those sometimes attributed to race, are often easily explained by an interaction between our biology and our culture. David Rowe and his colleagues (1994, 1995) illustrated this with an analogy: Black men tend to have higher blood pressure than White men. Suppose that (1) in both groups, salt consumption correlates with blood pressure, and (2) salt consumption is higher among Black men than among White men. The blood pressure “race difference” might then actually be, at least partly, a *diet* difference—a cultural preference for certain foods.

And that, said Rowe and his colleagues, parallels psychological findings. Although Latino, Asian, Black, White, and Native Americans differ in school achievement and delinquency, the differences are “no more than skin deep.” To the extent that family structure and economics, peer influences, and parental education predict behavior in one of these ethnic groups, they do so for the others as well.

So as members of different ethnic and cultural groups, we may differ in surface ways. But as members of one species we are subject to the same psychological forces. Our outward reactions vary, yet our basic emotions are

universal. Our tastes vary, yet they reflect common principles of hunger. Our social behaviors vary, yet they reflect pervasive principles of human influence. Cross-cultural research helps us appreciate both our cultural diversity *and* our human similarity.

“When [someone] has discovered why men in Bond Street wear black hats he will at the same moment have discovered why men in Timbuctoo wear red feathers.”

G. K. Chesterton, *Heretics*, 1905

RETRIEVAL PRACTICE

RP-9 How do people in individualist and collectivist cultures differ?

ANSWER: Individualists give priority to personal goals over group goals and tend to define their identity in terms of their own personal attributes. Collectivists give priority to group goals over individual goals and tend to define their identity in terms of group identifications.

Gender Development

LOQ 4-13 How does the meaning of *gender* differ from the meaning of *sex*?

We humans share an irresistible urge to organize our worlds into simple categories. Among the ways we classify people—as tall or short, dull or smart, cheerful or churlish—one stands out. Immediately after your birth (or before), everyone wanted to know, “Boy or girl?” Your parents may have offered clues with pink or blue clothing. Their answer described your [sex](#), your biological status, defined by your chromosomes and anatomy. For most people, those biological traits help define their assigned [gender](#), their culture’s expectations about what it means to be a man or a woman.

sex in psychology, the biologically influenced characteristics by which people define *male* and *female*.

gender in psychology, the socially influenced characteristics by which people define *boy*, *girl*, *man*, and *woman*.

Simply said, your body defines your sex. Your mind defines your gender. But your mind's understanding of gender arises from the interplay between your biology and your experiences (Eagly & Wood, 2013). Before we consider that interplay in more detail, let's take a closer look at some ways that males and females are both similar and different.

Pink and blue baby outfits illustrate how cultural norms vary and change. “The generally accepted rule is pink for the boy and blue for the girl,” declared the *Earnshaw's Infants' Department* in 1918 (Frassanito & Pettorini, 2008). “Pink being a more decided and stronger color is more suitable for the boy, while blue, which is more delicate and dainty, is prettier for the girls.”

Similarities and Differences

LOQ 4-14 What are some ways in which males and females tend to be alike and to differ?

Whether male or female, each of us receives 23 chromosomes from our mother and 23 from our father. Of those 46 chromosomes, 45 are *unisex*—the same for males and females. Our similar biology helped our evolutionary ancestors face similar adaptive challenges. Both men and women needed to survive, reproduce, and avoid predators, and so today we are in most ways alike. Survival for both men and women involved traveling long distances, and in today's ultramarathons men and women are similarly competitive. Identify yourself as male or female and you give no clues to your vocabulary, happiness, or ability to see, learn, and remember. Males and females, on average, have comparable creativity and intelligence and feel the same

emotions and longings (Hyde, 2014). Our “opposite” sex is, in reality, our very similar sex.

But in some areas, males and females do differ, and differences command attention. Some oft-noted differences (like the difference in self-esteem shown in [FIGURE 4.7](#)) are actually quite modest (Zell et al., 2015). Others are more striking. The average girl enters puberty about a year earlier than the average boy, and a woman’s life span is 5 years longer. She expresses emotions more freely, smiling and crying more, and, in Facebook updates, more often expresses “love” and being “sooo excited!!!” (Fischer & LaFrance, 2015; Schwartz et al., 2013). She can detect fainter odors, receives offers of help more often, and can become sexually re-aroused sooner after orgasm. She also has twice the risk of developing depression and anxiety and 10 times the risk of developing an eating disorder. Yet the average man is 4 times more likely to die by suicide or to develop an alcohol use disorder. His “more likely” list also includes autism spectrum disorder, color-deficient vision, and attention-deficit/hyperactivity disorder (ADHD). And as an adult, he is more at risk for antisocial personality disorder. Male or female, each has its own share of risks.

FIGURE 4.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 4.7 Much ado about a small difference in self-esteem

These two normal distributions differ by the approximate magnitude (0.21 standard deviation) of the sex difference in self-esteem, averaged over all available samples (Hyde, 2005). Moreover, such comparisons illustrate differences between the *average* female and male. The

variation *among* individual females or *among* individual males greatly exceeds this difference.

Gender similarities and differences appear throughout this book, but for now let's take a closer look at three gender differences. Although individuals vary widely, the *average* male and female differ in aggression, social power, and social connectedness.

AGGRESSION To a psychologist, [aggression](#) is any physical or verbal behavior intended to hurt someone physically or emotionally. Think of examples of aggressive people. Are most of them men? Likely yes. Men generally admit to more aggression, especially extreme physical violence (Bushman & Huesmann, 2010; Wölfer & Hewstone, 2015). In romantic relationships between men and women, minor acts of physical aggression, such as slaps, are roughly equal, but the most violent acts are mostly committed by men (Archer, 2000; Johnson, 2008).

aggression any physical or verbal behavior intended to harm someone physically or emotionally.

Laboratory experiments confirm a gender difference in aggression. Men have been more willing to blast people with what they believed was intense and prolonged noise (Bushman et al., 2007). And outside the laboratory, men—worldwide—commit more violent crime (Antonaccio et al., 2011; Caddick & Porter, 2012; Frisell et al., 2012). They also take the lead in hunting, fighting, warring, and supporting war (Liddle et al., 2012; Wood & Eagly, 2002, 2007).

Here's another question: Think of examples of people harming others by passing along hurtful gossip, or by shutting someone out of a social group or situation. Were most of those people men? Perhaps not. Those behaviors are acts of [relational aggression](#), and women are slightly more likely than men to commit them (Archer, 2004, 2007, 2009).

relational aggression an act of aggression (physical or verbal) intended to harm a person's relationship or social standing.

Amy Sancetta/AP Images

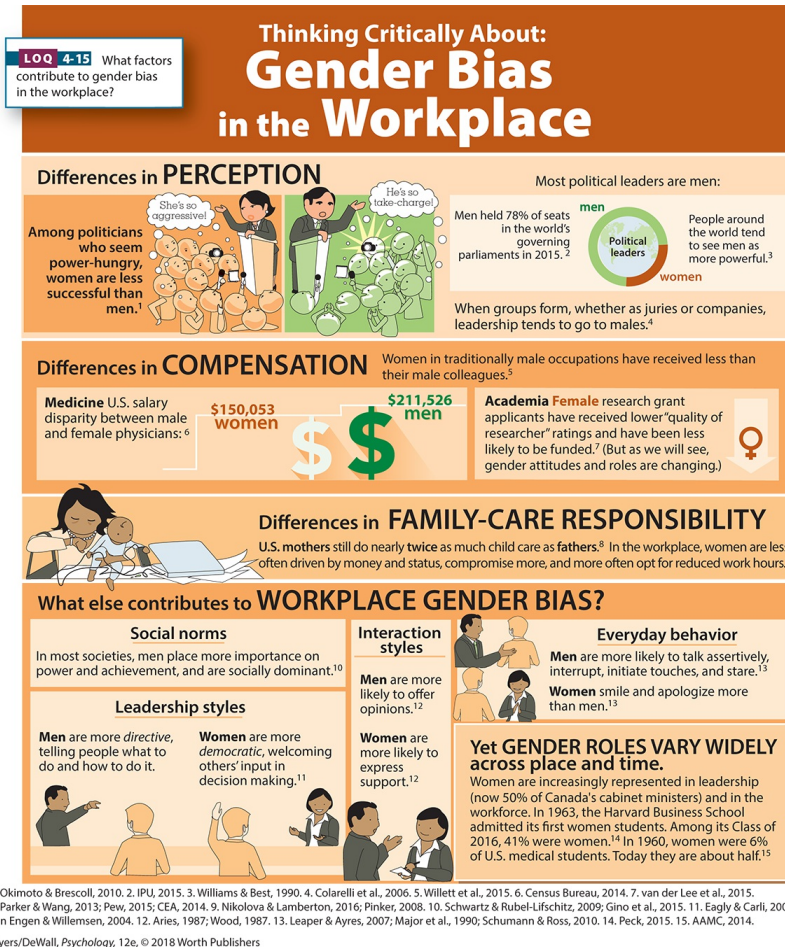

Deadly relational aggression

Sladjana Vidovic was a high school student who committed suicide after suffering constant relational aggression by bullies.

SOCIAL POWER Imagine you've walked into a job interview and are taking your first look at the two interviewers. The unsmiling person on the left oozes self-confidence and independence, maintaining steady eye contact. The person on the right gives you a warm, welcoming smile, making less eye contact and seeming to expect the other interviewer to take the lead.

Which interviewer is male?

If you said the person on the left, you're not alone. Around the world, from Nigeria to New Zealand, people have perceived gender differences in power (Williams & Best, 1990). For more on this topic, see [Thinking Critically About: Gender Bias in the Workplace](#).

SOCIAL CONNECTEDNESS Whether male or female, we all have a need to belong, though we may satisfy this need in different ways (Baumeister, 2010). Males tend to be *independent*. Even as children, males typically form large play groups that brim with activity and competition, with little intimate discussion (Rose & Rudolph, 2006). As adults, men enjoy side-by-side activities, and their conversations often focus on problem solving (Tannen, 1990; Wright, 1989). When asked a difficult question—"Do you have any idea why the sky is blue?"—men are more likely than women to hazard answers than to admit they don't know, a phenomenon researchers have called the *male answer syndrome* (Giuliano et al., 1998).

Scans of more than 1400 brains show no striking sex differences: "Human brains cannot be categorized into two distinct classes—male brain/female brain" (Joel et al., 2015). Brain scans do, however, suggest that a woman's brain, more than a man's, is wired in a way that enables social relationships (Ingallhalikar et al., 2013). This helps explain why females tend to be more *interdependent*. In childhood, girls usually play in small groups, often with

one friend. They compete less and imitate social relationships more (Maccoby, 1990; Roberts, 1991). Teen girls spend more time with friends and less time alone (Wong & Csikszentmihalyi, 1991). In late adolescence, they spend more time on social networking sites, and average twice as many text messages per day as boys (Lenhart, 2015a; Pryor et al., 2007, 2011). Girls' and women's friendships are more intimate, with more conversation that explores relationships (Maccoby, 2002). In one analysis of 10 million Facebook posts, women's status updates were as assertive as men's, but used warmer words, while men more often swore or expressed anger (Park et al., 2016). An analysis of over 700 million Facebook words found women also used more family-related words, whereas men used more work-related words (Schwartz et al., 2013).

Question: Why does it take 200 million sperm to fertilize one egg?

Answer: Because they won't stop for directions.

A gender difference in communication style was apparent in one New Zealand study of student e-mails. Two-thirds of the time people correctly guessed whether the author was male or female (Thomson & Murachver, 2001). In France, women have been found to make 63 percent of phone calls and, when talking to a woman, to stay connected longer (7.2 minutes) than men did when talking to other men (4.6 minutes) (Smoreda & Licoppe, 2000).

Do such findings mean that women are just more talkative? *No*. In another study, researchers counted the number of words 396 college students spoke in an average day (Mehl et al., 2007). Not surprisingly, the participants' talkativeness varied enormously—by 45,000 words between the most and least talkative. (How many words would you guess you speak a day?) Contrary to stereotypes of wordy women, both men and women averaged about 16,000 words daily.

Spoken words may not peg women or men as more talkative, but they do open windows on our interests. More than a half-million people's responses to various interest inventories reveal that “men prefer working with things and women prefer working with people” (Su et al., 2009). On entering American colleges, men are seven times more likely than women to express

interest in computer science (Pryor et al., 2011).

When searching for understanding from someone who will share their worries and hurts, people usually turn to women. Both men and women have reported that their friendships with women are more intimate, enjoyable, and nurturing (Kuttler et al., 1999; Rubin, 1985; Sapadin, 1988). Bonds and feelings of support are stronger among women than among men (Rossi & Rossi, 1993). Women's ties—as mothers, daughters, sisters, aunts, and grandmothers—bind families together. As friends, women talk more often and more openly (Berndt, 1992; Dindia & Allen, 1992). “Perhaps because of [women's] greater desire for intimacy,” reported Joyce Benenson and colleagues (2009), first-year college and university women are twice as likely as men to change roommates. And how do they cope with stress? Compared with men, women are more likely to turn to others for support. They are said to *tend and befriend* (Tamres et al., 2002; Taylor, 2002).

Anthony Asael/Danita Delimont Stock Photography; © 2/Rob Van Petten/Ocean/Corbis

Every man for himself, or tend and befriend?

Sex differences in the way we interact with others begin to appear at a very young age.

As empowered people generally do, men value freedom and self-reliance, which may help explain why men of all ages, worldwide, are less religious and pray less (Benson, 1992; Stark, 2002). Men also dominate the ranks of professional skeptics. All 10 winners and 14 runners-up on the *Skeptical Inquirer* list of outstanding twentieth-century rationalist skeptics were men. The Science and the Paranormal section of the 2010 Prometheus Books catalog (from the leading publisher of skepticism) included 98 male and 4 female authors. Women are far more likely to author books on spirituality.

Gender differences in both social connectedness and power are greatest in

late adolescence and early adulthood—the prime years for dating and mating. By their teen years, girls become less assertive and more flirtatious, and boys appear more dominant and less expressive (Chaplin, 2015). In adulthood, after the birth of a first child, attitude and behavior differences often peak. Mothers especially may become more traditional (Ferriman et al., 2009; Katz-Wise et al., 2010). By age 50, most parenting-related gender differences subside. Men become less domineering and more empathic, and women—especially those with paid employment—become more assertive and self-confident (Kasen et al., 2006; Maccoby, 1998). Worldwide, fewer women than men work full-time for an employer (19 percent versus 33 percent), but are similarly more satisfied with their lives when employed rather than unemployed (Ryan, 2016).

So, although women and men are more alike than different, there are some behavior differences between the average woman and man. Are such differences dictated by our biology? Shaped by our cultures and other experiences? Do we vary in the extent to which we are male or female? Read on.

“In the long years liker must they grow;
The man be more of woman, she of man.”

Alfred Lord Tennyson, *The Princess*, 1847

RETRIEVAL PRACTICE

RP-10 _____ (Men/Women) are more likely to commit relational aggression, and _____ (men/women) are more likely to commit physical aggression.

ANSWER: Women; men

The Nature of Gender: Our Biological Sex

LOQ 4-16 How do sex hormones influence prenatal and adolescent sexual development, and what is an *intersex* condition?

In most physical ways—regulating heat with sweat, preferring energy-rich foods, growing calluses where the skin meets friction—men and women are similar. When looking for a mate, men and women also prize many of the same traits—someone who is kind, honest, and intelligent. But in some mating-related domains, say evolutionary psychologists, guys act like guys whether they're chimpanzees or elephants, rural peasants or corporate presidents (Geary, 2010).

Biology does not *dictate* gender. But in two ways, biology *influences* gender:

- *Genetically*—males and females have differing *sex chromosomes*.
- *Physiologically*—males and females have differing concentrations of *sex hormones*, which trigger other anatomical differences.

These two influences began to form you long before you were born.

PRENATAL SEXUAL DEVELOPMENT Six weeks after you were conceived, you and someone of the other sex looked much the same. Then, as your genes kicked in, your biological sex—determined by your twenty-third pair of chromosomes (the two sex chromosomes)—became more apparent. Whether you are male or female, your mother's contribution to that chromosome pair was an [X chromosome](#). From your father, you received the 1 chromosome out of 46 that is not unisex—either another X chromosome, making you female, or a [Y chromosome](#), making you male.

X chromosome the sex chromosome found in both males and females. Females typically have two X chromosomes; males typically have one. An X chromosome from each parent produces a female child.

Y chromosome the sex chromosome typically found only in males. When paired with an X chromosome from the mother, it produces a male child.

About seven weeks after conception, a single gene on the Y chromosome throws a master switch, which triggers the testes to develop and to produce [testosterone](#), the main androgen (male hormone) that promotes male sex organ development. (Females also have testosterone, but less of it.)

testosterone the most important male sex hormone. Both males and females have it, but the additional testosterone in males stimulates the growth of the male sex organs during the fetal period, and the development of the male sex characteristics during puberty.

Later, during the fourth and fifth prenatal months, sex hormones bathe the fetal brain and influence its wiring. Different patterns for males and females develop under the influence of the male's greater testosterone and the female's ovarian hormones (Hines, 2004; Udry, 2000). If, however, females are prenatally exposed to unusually high levels of male hormones, they tend to grow up with more male-typical activity interests (Endendijk et al., 2016). Prenatal hormones help sculpt what we love to do.

ADOLESCENT SEXUAL DEVELOPMENT A flood of hormones triggers another period of dramatic physical change during adolescence, when boys and girls enter **puberty**. In this two-year period of rapid sexual maturation, pronounced male-female differences emerge. A variety of changes begin at about age 11 in girls and at about age 12 in boys, though the subtle beginnings of puberty, such as enlarging testes, appear earlier (Herman-Giddens et al., 2012). A year or two before the physical changes are visible, girls and boys often feel the first stirrings of sexual attraction (McClintock & Herdt, 1996).

puberty the period of sexual maturation, when a person becomes capable of reproducing.

Girls' slightly earlier entry into puberty can at first propel them to greater height than boys of the same age (**FIGURE 4.8**). But boys catch up when they begin puberty, and by age 14, they are usually taller than girls. During these growth spurts, the **primary sex characteristics**—the reproductive organs and external genitalia—develop dramatically. So do the nonreproductive **secondary sex characteristics**. Girls develop breasts and larger hips. Boys' facial hair begins growing and their voices deepen. Pubic and underarm hair emerges in both girls and boys (**FIGURE 4.9**).

FIGURE 4.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Tanner, 1978; Marili Forastieri/Getty Images

FIGURE 4.8 Height differences

Throughout childhood, boys and girls are similar in height. At puberty, girls surge ahead briefly, but then boys typically overtake them at about age 14. (Data from Tanner, 1978.)

primary sex characteristics the body structures (ovaries, testes, and external genitalia) that make sexual reproduction possible.

secondary sex characteristics nonreproductive sexual traits, such as female breasts and hips, male voice quality, and body hair.

FIGURE 4.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 4.9 Body changes at puberty

At about age 11 in girls and age 12 in boys, a surge of hormones triggers a variety of visible physical changes.

For boys, puberty's landmark is the first ejaculation, which often occurs first during sleep (as a "wet dream"). This event, called **spermarche**, usually

happens by about age 14.

spermarche [sper-MAR-key] the first ejaculation.

In girls, the landmark is the first menstrual period, **menarche**, usually within a year of age 12½ (Anderson et al., 2003). Genes play a major role in predicting when girls experience menarche (Perry et al., 2014). But environment matters, too. Early menarche is more likely following stresses related to father absence, sexual abuse, insecure attachments, or a history of a mother's smoking during pregnancy (Rickard et al., 2014; Shrestha et al., 2011; Sung et al., 2016). In various countries, girls are developing breasts earlier (sometimes before age 10) and reaching puberty earlier than in the past. Suspected triggers include increased body fat, diets filled with hormone-mimicking chemicals, and, possibly, greater stress due to family disruption (Biro et al., 2010, 2012; Ellis et al., 2012; Herman-Giddens, 2013).

menarche [meh-NAR-key] the first menstrual period.

Pubertal boys may not at first like their sparse beard. (But then it grows on them.)

Girls prepared for menarche usually view it as a positive life transition (Chang et al., 2009). Males report mostly positive emotional reactions to spermarche (Fuller & Downs, 1990).

RETRIEVAL PRACTICE

RP-11 Prenatal sexual development begins about _____ weeks after conception. Adolescence is marked by the onset of _____.

ANSWER: seven; puberty

For a 7-minute discussion of sexual development, see the **Video: Gender Development**.

SEXUAL DEVELOPMENT VARIATIONS Nature may blur the biological line between males and females. [Intersex](#) individuals may be born with unusual combinations of male and female chromosomes, hormones, and anatomy. For example, a genetic male may be born with normal male hormones and testes but no penis or a very small one. Such individuals may struggle with their gender identity.

intersex a condition present at birth due to unusual combinations of male and female chromosomes, hormones, and anatomy; possessing biological sexual characteristics of both sexes.

In the past, medical professionals often recommended *sex-reassignment surgery* to create an unambiguous sex identity for some children with this condition. One study reviewed 14 cases of genetic boys who had undergone early surgery and been raised as girls. Of those cases, 6 had later declared themselves male, 5 were living as females, and 3 reported an unclear male or female identity (Reiner & Gearhart, 2004).

Michael Dalder/
SEMENYA Reuters Newscom

“I am who I am.”

Dramatic improvements in South African track star Caster Semenya's race times prompted the International Association of Athletics Federations to undertake sex testing in 2009. Semenya was reported to have physical characteristics not typically male or female. She was officially cleared to continue competing as a woman. Semenya declared, “God made me the way I am and I accept myself. I am who I am” (YOU, 2009). In 2016, she won an Olympic gold medal.

In one famous case, a little boy lost his penis during a botched circumcision. His parents followed a psychiatrist's advice to raise him as a girl rather than as a damaged boy. So, with male chromosomes and hormones and female upbringing, did nature or nurture form this child's gender identity? Although raised as a girl, “Brenda” Reimer was not like most other girls. “She” didn't like dolls. She tore her dresses with rough-and-tumble play. At puberty she wanted no part of kissing boys. Finally, Brenda's parents explained what had happened, whereupon Brenda immediately rejected the assigned female identity. He cut his hair and chose a male name, David. He eventually married a woman and became a stepfather. Sadly, he later

committed suicide (Colapinto, 2000). Today, experts generally recommend postponing surgery until a child's naturally developing physical appearance and gender identity become clear.

The bottom line: "Sex matters," concluded the National Academy of Sciences (2001). Sex-related genes and physiology "result in behavioral and cognitive differences between males and females." Yet environmental factors matter, too, as we will see next. Nature and nurture work together.

The Nurture of Gender: Our Culture and Experiences

LOQ 4-17 How do gender roles and gender identity differ?

For many people, biological sex and gender coexist in harmony. Biology draws the outline, and culture paints the details. The physical traits that define a newborn as male or female are the same worldwide. But the gender traits that define how men (or boys) and women (or girls) should act, interact, or feel about themselves differ across time and place (Zentner & Eagly, 2015).

"Sex brought us together, but gender drove us apart."

New Yorker Collection, 2001,
Barbara Smaller from cartoonbank.com.

GENDER ROLES Cultures shape our behaviors by defining how we ought to behave in a particular social position, or [role](#). We can see this shaping

power in **gender roles**—the social expectations that guide our behavior as men or as women.

role a set of expectations (norms) about a social position, defining how those in the position ought to behave.

gender role a set of expected behaviors, attitudes, and traits for males or for females.

Dinodia/The Image Works

The gendered tsunami

In Sri Lanka, Indonesia, and India, the gendered division of labor helps explain the excess of female deaths from the 2004 tsunami. In some villages, 80 percent of those killed were women, who were mostly at home while the men were more likely to be at sea fishing or doing outdoor chores (Oxfam, 2005).

In just a thin slice of history, gender roles worldwide have undergone an extreme makeover. At the beginning of the twentieth century, only one country in the world—New Zealand—granted women the right to vote (Briscoe, 1997). By 2015, all countries granted that right. A century ago, American women could not vote in national elections, serve in the military, or divorce a husband without cause. And if a woman worked for pay, she would more likely have been a midwife or a seamstress than a surgeon or a

college professor. Now, more U.S. women than men graduate from college, and nearly half the workforce is female (DOL, 2015). In the STEM fields (Science, Technology, Engineering, and Mathematics), men currently hold most faculty positions (Ceci et al., 2014; Sheltzer & Smith, 2014). But when researchers invited U.S. professors to recommend candidates for STEM positions, most said they preferred hiring the highly qualified women over the equally qualified men (Williams & Ceci, 2015). The modern economy has produced jobs that rely not on brute strength but on social intelligence, open communication, and the ability to sit still and focus (Rosin, 2010).

Nomadic societies of food-gathering people have had little division of labor by sex. Boys and girls receive much the same upbringing. In agricultural societies, where women typically work in the nearby fields and men roam while herding livestock, cultures have shaped children to assume more distinct gender roles (Segall et al., 1990; Van Leeuwen, 1978).

Take a minute to check your own gender expectations. Would you agree that “When jobs are scarce, men should have more rights to a job”? In the United States, Britain, and Spain, barely over 12 percent of adults agree. In Nigeria, Pakistan, and India, about 80 percent of adults agree (Pew, 2010). We’re all human, but my, how our views differ. Northern European countries offer the greatest gender equity, Middle Eastern and North African countries the least (UN, 2015a).

Women’s 2016 representations in national parliaments ranged from 14 percent in the Pacific region to 41 percent in Scandinavia (IPU, 2016).

“You cannot put women and men on an equal footing. It is against nature.”

Turkish President Recep Tayyip Erdoğan, 2014

RETRIEVAL PRACTICE

RP-12 What are gender roles, and what do their variations tell us about our human capacity for learning and adaptation?

ANSWER: *Gender roles* are social rules or norms for accepted and

expected female and male behaviors. The norms associated with various roles, including gender roles, vary widely in different cultural contexts, which is proof that we are able to learn and adapt to the social demands of different environments.

HOW DO WE LEARN GENDER? A *gender role* describes how others expect us to think, feel, and act. Our **gender identity** is our personal sense of being male, female, or, occasionally, some combination of the two. How do we develop that personal viewpoint?

gender identity our sense of being male, female, or some combination of the two.

Social learning theory assumes that we acquire our identity in childhood, by observing and imitating others' gender-linked behaviors and by being rewarded or punished for acting in certain ways. ("Tatiana, you're such a good mommy to your dolls"; "Big boys don't cry, Armand.") But some critics think there's more to gender identity than imitating parents and being repeatedly rewarded for certain responses. They point out that **gender typing**—taking on a traditional male or female role—varies from child to child (Tobin et al., 2010).

social learning theory the theory that we learn social behavior by observing and imitating and by being rewarded or punished.

gender typing the acquisition of a traditional masculine or feminine role.

"We need to keep changing the attitude that raises our girls to be demure and our boys to be assertive, that criticizes our daughters for speaking out and our sons for shedding a tear."

Former President Barack Obama, 2016

Parents do help to transmit their culture's views on gender. In one analysis of 43 studies, parents with traditional gender views were more likely to have gender-typed children who shared their culture's expectations about how males and females should act (Tenenbaum & Leaper, 2002). When fathers share equally in housework, their daughters develop higher aspirations for work outside the home (Croft et al., 2014).

But no matter how much parents encourage or discourage traditional gender behavior, children may drift toward what feels right to them. Some organize themselves into “boy worlds” and “girl worlds,” each guided by their understanding of the rules. Others conform to these rules more flexibly. Still others seem to prefer **androgyny**: A blend of male and female roles feels right to them. Androgyny has benefits. As adults, androgynous people are more adaptable. They are more flexible in their actions and in their career choices (Bem, 1993). They tend to be more resilient and self-accepting, and they experience less depression (Lam & McBride-Chang, 2007; Mosher & Danoff-Burg, 2008; Ward, 2000).

androgyny displaying both traditional masculine and feminine psychological characteristics.

Feelings matter, but so does how we think. Early in life, we all form *schemas*, or concepts that help us make sense of our world. Our *gender schemas* organize our experiences of male-female characteristics and help us think about our gender identity, about who we are (Bem, 1987, 1993; Martin et al., 2002).

As young children, we were “gender detectives” (Martin & Ruble, 2004). Before our first birthday, we knew the difference between a male and female voice or face (Martin et al., 2002). After we turned 2, language forced us to label the world in terms of gender. English classifies people as *he* and *she*. Other languages classify objects as masculine (“*le* train”) or feminine (“*la* table”).

Courtesy of David Myers

The social learning of gender

Children observe and imitate parental models.

Once children grasp that two sorts of people exist—and that they are of one of these two sorts—they search for clues about gender. In every culture, people communicate their gender in many ways. Their *gender expression* drops hints not only in their language but also in their clothing, interests, and possessions. Having picked up such clues, 3-year-olds may divide the human world in half. They will then like their own kind better and seek them out for play. “Girls,” they may decide, are the ones who watch *My Little Pony* and have long hair. “Boys” watch *Transformers* and don’t wear dresses. Armed with their newly collected “proof,” they then adjust their behaviors to fit their concept of gender. These stereotypes are most rigid at about age 5 or 6. If the new neighbor is a girl, a 6-year-old boy may assume he cannot share her interests. For young children, gender looms large.

For a [transgender](#) person, gender identity differs from the behaviors or traits considered typical for that person’s birth-designated sex (APA, 2010; Bockting, 2014). Even as 5- to 12-year-olds, transgender children typically view themselves in terms of their expressed gender rather than their birth-designated sex (Olson et al., 2015b). From childhood onward, a person may feel like a male in a female body, or a female in a male body. Biologist Robert Sapolsky (2015) explains: “It’s not that [these] individuals think they

are a different gender than they actually are. It's that they [are] stuck with bodies that are a different gender from who they actually are."

transgender an umbrella term describing people whose gender identity or expression differs from that associated with their birth-designated sex.

Colin McPherson/Getty Images

"My father . . . is . . . a woman."

So said Mark Morris (2015) of his famous parent, the transgender Welsh writer Jan Morris. After gender reassignment surgery in 1973, Jan Morris was forced by law to divorce Mark's mother. "They continued to live together in a remarkably strong marital bond," until remarrying when same-sex marriages became legal in Britain.

In most countries, it's not easy being transgender. In a national survey of lesbian, gay, bisexual, and transgender Americans, 71 percent saw "some" or "a lot" of social acceptance for gay men, and 85 percent said the same for lesbians. But only 18 percent saw similar acceptance for transgender people (Sandstrom, 2015), who number about 1.4 million in the United States (Flores et al., 2016). And that is the experience of transgender people—46 percent of whom, in a survey of 27,175 transgender Americans, reported being verbally harassed in the last year (James et al., 2016). The psychiatric profession no longer considers gender nonconformity as a mental disorder, and thus no longer labels transgender people as having a "gender identity

disorder.” But some transgender people (not surprisingly, given the social disapproval) may experience profound distress and be diagnosed with *gender dysphoria*.

Transgender people may attempt to align their outward appearance and everyday lives with their internal gender identity. Brain scans reveal that those who seek medical sex-reassignment have some neural tracts that differ from those whose gender identity matches their birth-designated sex (Kranz et al., 2014; Van Kesteren et al., 1997). Note that *gender identity* is distinct from *sexual orientation* (the direction of one’s sexual attraction). Transgender people may be sexually attracted to people of the other gender, the same gender, both genders, or to no one at all. Your sexual orientation, as some say, is who you fantasize going to bed *with*; your gender identity is who you go to bed *as*.

For a 6.5-minute exploration of one pioneering transgender person’s journey, see the **Video: Renée Richards—A Long Journey**.

Reflections on Nature, Nurture, and Their Interaction

LOQ 4-18 How do nature, nurture, and our own choices influence gender roles?

“There are trivial truths and great truths,” reflected the physicist Niels Bohr on the paradoxes of science. “The opposite of a trivial truth is plainly false. The opposite of a great truth is also true.” Our ancestral history helped form us as a species. Where there is variation, natural selection, and heredity, there will be evolution. The unique gene combination created when our mother’s egg engulfed our father’s sperm predisposed both our shared humanity and our individual differences. Our genes form us. This is a great truth about human nature.

But our experiences also shape us. Our families and peer relationships teach us how to think and act. Differences initiated by our nature may be amplified by our nurture. If their genes and hormones predispose males to be more physically aggressive than females, culture can amplify this gender difference through norms that reward macho men and gentle women. If men

are encouraged toward roles that demand physical power, and women toward more nurturing roles, each may act accordingly. Roles remake their players. Presidents in time become more presidential, servants more servile. Gender roles similarly shape us.

In many modern cultures, gender roles are merging. Brute strength has become less important for power and status (think “philanthrocapitalists” Priscilla Chan and Mark Zuckerberg). From 1965 to 2016, women soared from 9 percent to 47 percent of U.S. medical students (AAMC, 2014, 2016). In 1965, U.S. married women devoted eight times as many hours to housework as did their husbands; by 2012, this gap had shrunk to less than twice as many (Parker & Wang, 2013; Sayer, 2016). Such swift changes signal that biology does not fix gender roles.

If nature and nurture jointly form us, are we “nothing but” the product of nature and nurture? Are we rigidly determined?

San Diego Museum of Man,
photograph by Rose Tyson

Culture matters

As this exhibit at San Diego's Museum of Man illustrates, children learn their culture. A baby's foot can step into any culture.

We *are* the product of nature and nurture, but we are also an open system ([FIGURE 4.10](#)). Genes are all-pervasive but not all-powerful. People may reject their evolutionary role as transmitters of genes and choose not to reproduce. Culture, too, is all-pervasive but not all-powerful. People may

defy peer pressures and resist social expectations.

FIGURE 4.10 The biopsychosocial approach to development

Moreover, we cannot excuse our failings by blaming them solely on bad genes or bad influences. In reality, we are both creatures and creators of our worlds. So many things about us—including our gender roles—are the products of our genes and environments. Yet the stream that runs into the future flows through our present choices. Our decisions today design our environments tomorrow. The human environment is not like the weather—something that just happens. We are its architects. Our hopes, goals, and expectations influence our destiny. And that is what enables cultures to vary and to change. Mind matters.

RETRIEVAL PRACTICE

RP-13 How does the biopsychosocial approach explain our individual development?

ANSWER: The biopsychosocial approach considers all the factors that influence our individual development: biological factors (including evolution and our genes, hormones, and brain), psychological factors (including our experiences, beliefs, feelings, and expectations), and social-cultural factors (including parental and peer influences, cultural individualism or collectivism, and gender norms).

* * *

We know from our correspondence and from surveys that some readers are troubled by the naturalism and evolutionism of contemporary science. (A note to readers from other nations: In the United States there is a wide gulf between scientific and lay thinking about evolution.) “The idea that human minds are the product of evolution is . . . unassailable fact,” declared a 2007 editorial in *Nature*, a leading science journal. In *The Language of God*, Human Genome Project director Francis Collins (2006, pp. 141, 146), a self-described evangelical Christian, compiled the “utterly compelling” evidence that led him to conclude that Darwin’s big idea is “unquestionably correct.” Yet Gallup pollsters have reported that 42 percent of U.S. adults believe that humans were created “pretty much in their present form” within the last 10,000 years (Newport, 2014). Many people who dispute the scientific story worry that a science of behavior (and evolutionary science in particular) will destroy our sense of the beauty, mystery, and spiritual significance of the human creature. For those concerned, we offer some reassuring thoughts.

“Let’s hope that it’s not true; but if it is true, let’s hope that it doesn’t become widely known.”

Lady Ashley, commenting on Darwin’s theory

When Isaac Newton explained the rainbow in terms of light of differing wavelengths, the British poet John Keats feared that Newton had destroyed the rainbow’s mysterious beauty. Yet, as evolutionary biologist Richard Dawkins (1998) noted in *Unweaving the Rainbow*, Newton’s analysis led to an even deeper mystery—Einstein’s theory of special relativity. Nothing about Newton’s optics need diminish our appreciation for the dramatic elegance of a rainbow arching across a brightening sky.

“Is it not stirring to understand how the world actually works—that white light is made of colors, that color measures light waves, that transparent air reflects light . . . ? It does no harm to the romance of the sunset to know a little about it.”

Carl Sagan, *Skies of Other Worlds*, 1988

When Galileo assembled evidence that the Earth revolved around the Sun, not vice versa, he did not offer irrefutable proof for his theory. Rather, he offered a coherent explanation for a variety of observations, such as the changing shadows cast by the Moon's mountains. His explanation eventually won the day because it described and explained things in a way that made sense, that hung together. Darwin's theory of evolution likewise is a coherent view of natural history. It offers an organizing principle that unifies various observations.

Many people of faith find the scientific idea of human origins congenial with their spirituality. In the fifth century, St. Augustine (quoted by Wilford, 1999) wrote, "The universe was brought into being in a less than fully formed state, but was gifted with the capacity to transform itself from unformed matter into a truly marvelous array of structures and life forms." Some 1600 years later, Pope Francis in 2014 welcomed a science-religion dialogue, saying, "Evolution in nature is not inconsistent with the notion of creation, because evolution requires the creation of beings that evolve."

Meanwhile, many people of science are awestruck at the emerging understanding of the universe and the human creature. It boggles the mind—the entire universe popping out of a point some 14 billion years ago, and instantly inflating to cosmological size. Had the energy of this Big Bang been the tiniest bit less, the universe would have collapsed back on itself. Had it been the tiniest bit more, the result would have been a soup too thin to support life. Astronomer Sir Martin Rees has described *Just Six Numbers* (1999), any one of which, if changed ever so slightly, would produce a cosmos in which life could not exist. Had gravity been a tad stronger or weaker, or had the weight of a carbon proton been a wee bit different, our universe just wouldn't have worked.

What caused this almost-too-good-to-be-true, finely tuned universe? Why is there something rather than nothing? How did it come to be, in the words of Harvard-Smithsonian astrophysicist Owen Gingerich (1999), "so extraordinarily right, that it seemed the universe had been expressly designed to produce intelligent, sentient beings"? On such matters, a humble, awed, scientific silence is appropriate, suggested philosopher Ludwig Wittgenstein: "Whereof one cannot speak, thereof one must be silent" (1922, [p. 189](#)).

heromen30/Shutterstock

Rather than fearing science, we can welcome its enlarging our understanding and awakening our sense of awe. In *The Fragile Species*, Lewis Thomas (1992) described his utter amazement that the Earth in time gave rise to bacteria and eventually to Bach's Mass in B Minor. In a short 4 billion years, life on Earth has come from nothing to structures as complex as a 6-billion-unit strand of DNA and the incomprehensible intricacy of the human brain. Atoms no different from those in a rock somehow formed dynamic entities that produced extraordinary, self-replicating, information-processing systems—us (Davies, 2007). Although we appear to have been created from dust, over eons of time, the end result is a priceless creature, one rich with potential beyond our imagining.

“The causes of life's history [cannot] resolve the riddle of life's meaning.”

Stephen Jay Gould, *Rocks of Ages: Science and Religion in the Fullness of Life*, 1999

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Individualist cultures tend to value _____; collectivist cultures tend to value _____.

- a. interdependence; independence
- b. independence; interdependence
- c. solidarity; uniqueness
- d. duty; fulfillment

In psychology, _____ is the biologically influenced

characteristics by which people define male and female. The socially influenced characteristics by which people define boy, girl, man, and woman is _____.

Females and males are very similar to each other. But one way they differ is that

- a. females are more physically aggressive than males.
- b. males are more democratic than females in their leadership roles.
- c. as children, females tend to play in small groups, while males tend to play in large groups.
- d. females are more likely to commit suicide.

A fertilized egg will develop into a boy if it receives a/n _____ chromosome from its father.

Primary sex characteristics relate to _____; secondary sex characteristics refer to _____.

- a. spermatarche; menarche
- b. breasts and facial hair; ovaries and testes
- c. emotional maturity; hormone surges
- d. reproductive organs; nonreproductive traits

On average, girls begin puberty at about the age of _____, boys at about the age of _____.

A person born with sexual anatomy that differs from typical male or female anatomy may be considered _____.

Gender role refers to our

- a. personal sense of being male or female.
- b. culture's expectations about the "right" way for males and females to behave.
- c. assigned birth sex—our chromosomes and anatomy.
- d. unisex characteristics.

Our sense of being male, female, or some combination of the two is known as our _____.

Social Development

Life is a journey, from womb to tomb. So it is for me [DM], and so it will be for you. My story, and yours, began when a man and a woman together contributed 20,000+ genes to an egg that became a unique person. Those genes coded the protein building blocks that, with astonishing precision, formed our bodies and predisposed our traits. My grandmother bequeathed to my mother a rare hearing loss pattern, which she, in turn, gave to me (the least of her gifts). My father was an amiable extravert, and sometimes I forget to stop talking, even though as a child, my talking was impeded by painful stuttering (for which Seattle Public Schools provided speech therapy).

Along with my parents' nature, I also received their nurture. Like you, I was born into a particular family and culture, with its own way of viewing the world. My values have been shaped by a family culture filled with talking and laughter, by a religious culture that speaks of love and justice, and by an academic culture that encourages critical thinking (asking, *What do you mean? How do you know?*).

We are formed by our genes and by our contexts, so our stories will differ. But in many ways we are each like nearly everyone else on Earth. Being human, you and I have a need to belong. My mental video library, which began after age 4, is filled with scenes of social attachment. Over time, my attachments to parents loosened as peer friendships grew. After lacking confidence to date in high school, I fell in love with a college classmate and married at age 20. Natural selection predisposes us to survive and perpetuate our genes. Sure enough, two years later a child entered our lives, and I experienced a new form of love that surprised me with its intensity.

But life is marked by change. That child and his brother now live 2000 miles away, and their sister has found her calling in South Africa. The tight rubber bands linking parent and child have loosened, as yours likely have as well.

Change also marks most vocational lives, which for me transitioned from a teen working in the family insurance agency, to a premed chemistry major and hospital aide, to (after discarding my half-completed medical school

applications) a psychology professor and author. I predict that in 10 years you, too, will be doing things you do not currently anticipate.

Stability also marks our development: Our life situations change, but we experience a continuous self. When I look in the mirror, I do not see the person I once was, but I feel like the person I have always been. I am the same person who, as a late teen, played basketball and discovered love. A half-century later, I still play basketball and still love (with less passion but more security) the life partner with whom I have shared life's griefs and joys.

Continuity morphs through stages—growing up, raising children, enjoying a career, and, eventually, life's final stage, which will demand my presence. As I wend my way through this cycle of life and death, I am mindful that life is a journey, a continuing process of development, seeded by nature and shaped by nurture, animated by love and focused by work, begun with wide-eyed curiosity and completed, for those blessed to live to a good old age, with peace and never-ending hope.

Across the life span, we grow from newborn to toddler, from toddler to teenager, and from teenager to mature adult. At each stage of life there are physical, cognitive, and social milestones. We begin with prenatal development and the newborn. Then we'll turn our attention to infancy and childhood, adolescence, and adulthood.

Developmental Issues, Prenatal Development, and the Newborn

Developmental Psychology's Major Issues

LOQ LEARNING OBJECTIVE QUESTION 5-1 What three issues have engaged developmental psychologists?

Researchers find human development interesting for the same reasons most of the rest of us do—they want to understand more about how we've become our current selves, and how we may change in the years ahead.

[Developmental psychology](#) examines our physical, cognitive, and social development across the life span, with a focus on three major issues:

Nature and nurture: How does our genetic inheritance (our nature) interact with our experiences (our nurture) to influence our development? (This was our focus in [Chapter 4](#).)

Continuity and stages: What parts of development are gradual and continuous, like riding an escalator? What parts change abruptly in separate stages, like climbing rungs on a ladder?

“Nature is all that a man brings with him into the world; nurture is every influence that affects him after his birth.”

Francis Galton, *English Men of Science*, 1874

Stability and change: Which of our traits persist through life? How do we change as we age?

developmental psychology a branch of psychology that studies physical, cognitive, and social change throughout the life span.

Are there clear-cut stages of psychological development, as there are physical stages such as walking before running? The *stage theories* we will consider—of Jean Piaget on cognitive development, Lawrence Kohlberg on moral development, and Erik Erikson on psychosocial development—propose developmental stages (summarized in [FIGURE 5.1](#)). But as we will also see, some research casts doubt on the idea that life proceeds through neatly defined age-linked stages.

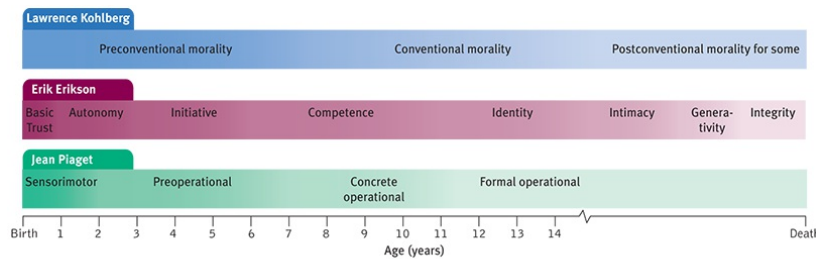

FIGURE 5.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.1 Comparing the stage theories

(With thanks to Dr. Sandra Gibbs, Muskegon Community College, for inspiring this illustration.)

Although many modern developmental psychologists do not identify as stage theorists, the stage concept remains useful. The human brain does experience growth spurts during childhood and puberty that correspond roughly to Piaget's stages (Thatcher et al., 1987). And stage theories contribute a developmental perspective on the whole life span, by suggesting how people of one age think and act differently when they arrive at a later age.

Stability and Change

As we follow lives through time, do we find more evidence for stability or change? If reunited with a long-lost grade-school friend, do we instantly realize that "it's the same old Andy"? Or do people we once befriended seem like strangers? (At least one acquaintance of mine [DM's] would choose the second option. At his 40-year college reunion, he failed to recognize a former classmate. The appalled classmate was his long-ago first wife!)

We experience both stability and change. Some of our characteristics, such as *temperament*, are very stable:

- One research team that studied 1000 people from ages 3 to 38 was struck by the consistency of temperament and emotionality across time (Moffitt et al., 2013; Slutske et al., 2012). Out-of-control 3-year-olds were the most likely to become teen smokers, adult criminals, or out-of-control gamblers. In another study, 6-year-old Canadian boys with conduct problems were four times more likely than other boys to be convicted of a violent crime by age 24 (Hodgins et al., 2013).

- Another research team showed that extraversion among British 16-year-olds predicted their future happiness as 60-year-olds (Gale et al., 2013). And the widest smilers in childhood and college photos are, years later, the ones most likely to enjoy enduring marriages (Hertenstein et al., 2009).
- A 40-year study found that responsible primary school children even outlive their out-of-control classmates (Spengler et al., 2016).

“As at 7, so at 70,” says a Jewish proverb. People predict that they will not change much in the future (Quoidbach et al., 2013). In some ways, they are right. As people grow older, personality gradually stabilizes (Briley & Tucker-Drob, 2014; Specht et al., 2014).

We cannot, however, predict all aspects of our future selves based on our early life. Our social attitudes, for example, are much less stable than our temperament, especially during the impressionable late adolescent years (Krosnick & Alwin, 1989; Rekker et al., 2015). Older children and adolescents learn new ways of coping. Although delinquent children have elevated rates of later problems, many confused and troubled children blossom into mature, successful adults (Moffitt et al., 2002; Roberts, B. W., et al., 2013; Thomas & Chess, 1986). Life is a process of becoming. Our present struggles may lay the foundation for a happier tomorrow.

Tom Prokop/Shutterstock; Photodisc/Getty Images

Smiles predict marital stability

In one study of 306 college alums, 1 in 4 with yearbook expressions like the one on the left later divorced, as did only 1 in 20 with smiles like the one on the right (Hertenstein et al., 2009).

The New Yorker Collection, 1998, Peter Mueller
from cartoonbank.com. All Rights Reserved.

As adults grow older, there is continuity of self.

In some ways, we *all* change with age. Most shy, fearful toddlers begin opening up by age 4, and most people become more conscientious, stable, agreeable, and self-confident in the years after adolescence (Lucas & Donnellan, 2009; Shaw et al., 2010; Van den Akker et al., 2014). Risk-prone adolescents tend to become more cautious adults (Mata et al., 2016). Indeed, many irresponsible 18-year-olds have matured into 40-year-old business or cultural leaders. (If you are the former, you aren't done yet.) Such changes can occur without changing a person's position *relative to others* of the same age. The hard-driving young adult may mellow by later life, yet still be a relatively driven senior citizen.

Life requires *both* stability and change. Stability provides our identity, enabling us to depend on others and on ourselves. Our potential for change gives us our hope for a brighter future, allowing us to adapt and grow with experience.

RETRIEVAL PRACTICE

RP-1 Developmental researchers who emphasize learning and experience are supporting _____; those who emphasize biological maturation are supporting _____.

ANSWER: continuity; stages.

RP-2 What findings in psychology support (1) the stage theory of

development and (2) the idea of stability in personality across the life span?

ANSWER: (1) Stage theory is supported by the work of Piaget (cognitive development), Kohlberg (moral development), and Erikson (psychosocial development). (2) Some traits, such as temperament, exhibit remarkable stability across many years.

Prenatal Development and the Newborn

LOQ 5-2 What is the course of prenatal development, and how do *teratogens* affect that development?

Conception

Nothing is more natural than a species reproducing itself. And nothing is more wondrous. For you, the process started inside your *grandmother*—as an egg formed inside a developing female inside of her. (Your mother was born with all the immature eggs she would ever have.) Your father, in contrast, began producing sperm cells nonstop at puberty—in the beginning at a rate of more than 1000 sperm during the second it takes to read this phrase.

Some time after puberty, your mother's ovary released a mature egg—a cell roughly the size of the period that ends this sentence. Like space voyagers approaching a huge planet, some 250 million deposited sperm began their frantic race upstream, approaching a cell 85,000 times their own size. The small number reaching the egg released digestive enzymes that ate away the egg's protective coating ([FIGURE 5.2a](#)). The one winning sperm penetrated the coating and was welcomed in ([Figure 5.2b](#)), the egg's surface blocking out the others. Before half a day elapsed, the egg nucleus and the sperm nucleus fused: The two became one.

FIGURE 5.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Eye of Science/Science Source; David M. Phillips/Science Source

FIGURE 5.2 Life is sexually transmitted

(a) Sperm cells surround an egg. (b) As one sperm penetrates the egg's jellylike outer coating, a series of chemical events begins that will cause sperm and egg to fuse into a single cell. If all goes well, that cell will subdivide again and again to emerge 9 months later as a 37-trillion-cell human being.

Consider it your most fortunate of moments. Among 250 million sperm, the one needed to make you, in combination with that one particular egg, won the race. And so it was for innumerable generations before us. If any one of our ancestors had been conceived with a different sperm or egg, or died before conceiving, or not chanced to meet their partner or. . . . The mind boggles at the improbable, unbroken chain of events that produced us.

Prenatal Development

How many fertilized eggs, called **zygotes**, survive beyond the first 2 weeks? Fewer than half (Grobstein, 1979; Hall, 2004). But for us, good fortune prevailed. One cell became 2, then 4—each just like the first—until this cell division had produced some 100 identical cells within the first week. Then the cells began to differentiate—to specialize in structure and function (“I’ll become a brain, you become intestines!”).

zygote the fertilized egg; it enters a 2-week period of rapid cell division and develops into an embryo.

Care to guess your body's total number of cells?

ANSWER: By one careful estimate, the average human has 37.2 trillion cells (Bianconi et al., 2013).

About 10 days after conception, the zygote attaches to the mother's uterine wall, beginning approximately 37 weeks of the closest human relationship. The zygote's inner cells become the **embryo** (FIGURE 5.3a). Many of its outer cells become the *placenta*, the life-link that transfers nutrients and oxygen from mother to embryo. Over the next 6 weeks, the embryo's organs begin to form and function. The heart begins to beat.

FIGURE 5.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.3 Prenatal development

(a) The embryo grows and develops rapidly. At 40 days, the spine is visible and the arms and legs are beginning to grow. (b) By the start of the ninth week, when the fetal period begins, facial features, hands, and feet have formed. (c) As the fetus enters the sixteenth week, its 3 ounces could fit in the palm of your hand.

embryo the developing human organism from about 2 weeks after fertilization through the second month.

By 9 weeks after conception, an embryo looks unmistakably human (Figure 5.3b). It is now a **fetus** (Latin for “offspring” or “young one”). During the sixth month, organs such as the stomach develop enough to give the fetus a good chance of surviving and thriving if born prematurely.

fetus the developing human organism from 9 weeks after conception to birth.

At each prenatal stage, genetic and environmental factors affect our development. By the sixth month, the fetus is responsive to sound. Microphone readings taken inside the uterus reveal that the fetus is exposed to the sound of its mother's muffled voice (Ecklund-Flores, 1992; Hepper, 2005). Immediately after emerging from their underwater world, newborns prefer their mother's voice to another woman's, or to their father's (DeCasper et al., 1986, 1994; Lee & Kisilevsky, 2014).

They also prefer hearing their mother's language. In one study, day-old American and Swedish newborns paused more in their pacifier sucking when listening to familiar vowels from their mother's language (Moon et al., 2013). After repeatedly hearing a fake word (*tatata*) in the womb, Finnish newborns' brain waves displayed recognition when hearing the word after birth (Partanen et al., 2013). If their mother spoke two languages during pregnancy, newborns displayed interest in both (Byers-Heinlein et al., 2010). And just after birth, babies born to French-speaking mothers tended to cry with the rising intonation of French; babies born to German-speaking mothers cried with the falling tones of German (Mampe et al., 2009). Would you have guessed? The learning of language begins in the womb.

moodboard/Cultura/Getty Images

Prenatal development

Zygote: Conception to 2 weeks

Embryo: 2 to 9 weeks

Fetus: 9 weeks to birth

In the two months before birth, fetuses demonstrate learning in other ways, as when they adapt to a vibrating, honking device placed on their mother's abdomen (Dirix et al., 2009). Like people who adapt to the sound of trains in their neighborhood, fetuses get used to the honking. Moreover, four weeks later, they recall the sound (as evidenced by their blasé response, compared with the reactions of those fetuses not previously exposed).

“You shall conceive and bear a son. So then drink no wine or strong drink.”

Judges 13:7

Sounds are not the only environmental factors that impact fetal development. In addition to transferring nutrients and oxygen from mother to fetus, the placenta screens out many harmful substances. But some slip by. **Teratogens**, agents such as viruses and drugs, can damage an embryo or fetus. This is one reason pregnant women are advised not to smoke or to drink alcohol. A pregnant woman never smokes or drinks alone. When alcohol enters her bloodstream, and that of her fetus, it reduces activity in both their central nervous systems. Alcohol use during pregnancy may prime the woman's offspring to like alcohol and put them at risk for heavy drinking and alcohol use disorder during their teen years. In experiments, when pregnant rats drank alcohol, their young offspring later displayed a liking for alcohol's taste and odor (Youngentob et al., 2007, 2009).

teratogens (literally, “monster makers”) agents, such as chemicals and viruses, that can reach the embryo or fetus during prenatal development and cause harm.

Even light drinking or occasional binge drinking can affect the fetal brain (Braun, 1996; Marjonen et al., 2015). Persistent heavy drinking puts the fetus at risk for a dangerously low birth weight, birth defects, future behavior problems, and lower intelligence. For 1 in about 700 children, the effects are visible as **fetal alcohol syndrome (FAS)**, the most serious of all fetal alcohol spectrum disorders, marked by lifelong physical and mental abnormalities (May et al., 2014). The fetal damage may occur because alcohol has an *epigenetic effect*: It leaves chemical marks on DNA that switch genes abnormally on or off (Liu et al., 2009). Smoking during pregnancy also leaves epigenetic scars that weaken infants' ability to handle stress (Stroud et al., 2014).

fetal alcohol syndrome (FAS) physical and cognitive abnormalities in children caused by a pregnant woman's heavy drinking. In severe cases, signs include a small, out-of-proportion head and abnormal facial features.

If a pregnant woman experiences extreme stress, the stress hormones flooding her body may indicate a survival threat to the fetus and produce an earlier delivery (Glynn & Sandman, 2011). Some stress early in life prepares us to cope with later adversity. But substantial prenatal stress exposure puts a child at increased risk for health problems such as hypertension, heart disease, obesity, and psychiatric disorders.

RETRIEVAL PRACTICE

RP-3 The first two weeks of prenatal development is the period of the _____. The period of the _____ lasts from 9 weeks after conception until birth. The time between those two prenatal periods is considered the period of the _____.

ANSWER: zygote; fetus; embryo

For an interactive review of prenatal development, see **PsychSim 6: Conception to Birth**. See also the 8-minute **Video: Prenatal Development**.

The Competent Newborn

LOQ 5-3 What are some newborn abilities, and how do researchers explore infants' mental abilities?

Babies come with apps preloaded. Having survived prenatal hazards, we as newborns came equipped with automatic reflex responses ideally suited for our survival. We withdrew our limbs to escape pain. If a cloth over our face interfered with our breathing, we turned our head from side to side and swiped at it.

New parents are often in awe of the coordinated sequence of reflexes by which their baby gets food. When something touches their cheek, babies turn toward that touch, open their mouth, and vigorously *root* for a nipple. Finding one, they automatically close on it and begin *sucking*. (Failing to find satisfaction, the hungry baby may cry—a behavior parents find highly unpleasant, and very rewarding to relieve.) Other adaptive reflexes include the *startle* reflex (when arms and legs spring out, quickly followed by fist clenching and loud crying) and the surprisingly strong *grasping* reflex, both of which may have helped infants stay close to their caregivers.

The pioneering American psychologist William James presumed that the newborn experiences a “blooming, buzzing confusion,” an assumption few people challenged until the 1960s. But then scientists discovered that babies can tell you a lot—if you know how to ask. To ask, you must capitalize on what babies can do—gaze, suck, and turn their heads. So, equipped with eye-tracking machines and pacifiers wired to electronic gear, researchers set out to answer parents' age-old questions: What can my baby see, hear, smell, and think?

“I felt like a man trapped in a woman's body. Then I was born.”

Comedian Chris Bliss

Consider how researchers exploit [habituation](#)—a decrease in responding with repeated stimulation. We saw this earlier when fetuses adapted to a vibrating, honking device placed on their mother's abdomen. The novel stimulus gets attention when first presented. With repetition, the response weakens. This seeming boredom with familiar stimuli gives us a way to ask

infants what they see and remember.

habituation decreasing responsiveness with repeated stimulation. As infants gain familiarity with repeated exposure to a stimulus, their interest wanes and they look away sooner.

Even as newborns, we prefer sights and sounds that facilitate social responsiveness. We turn our heads in the direction of human voices. We gaze longer at a drawing of a face-like image ([FIGURE 5.4](#)). We prefer to look at objects 8 to 12 inches away. Wonder of wonders, that just happens to be about the distance between a nursing infant's eyes and its mother's (Maurer & Maurer, 1988). Our brain's default settings help us connect socially.

FIGURE 5.4 Myers/DeWall, *Psychology*, 12e,

FIGURE 5.4 Newborns' preference for faces

When shown these two stimuli with the same three elements, Italian newborns spent nearly twice as many seconds looking at the face-like image (Johnson & Morton, 1991). Canadian newborns—average age 53 minutes in one study—displayed the same apparently inborn preference to look toward faces (Mondloch et al., 1999).

Within days after birth, our brain's neural networks were stamped with the smell of our mother's body. Week-old nursing babies, placed between a gauze pad from their mother's bra and one from another nursing mother, have usually turned toward the smell of their own mother's pad (MacFarlane, 1978). What's more, that smell preference lasts. One experiment capitalized on the fact that some nursing mothers in a French maternity ward used a chamomile-scented balm to prevent nipple soreness (Delaunay-El Allam et

al., 2010). Twenty-one months later, their toddlers preferred playing with chamomile-scented toys! Their peers who had not sniffed the scent while breast-feeding showed no such preference. (This makes us wonder: Will these children, who learned to associate chamomile with their mother's breast, grow up to become devoted chamomile tea drinkers?) Such studies reveal the remarkable abilities with which we enter our world.

Prepared to feed and eat

Animals are predisposed to respond to their offspring's cries for nourishment, even if they are in the middle of an ultramarathon, as I [ND] was when my 18-month-old Bevy decided that only Daddy could feed her.

RETRIEVAL PRACTICE

RP-4 Infants' _____ to repeated stimulation helps developmental psychologists study what they can learn and remember.

ANSWER: habituation

REVIEW Developmental Issues, Prenatal Development, and the Newborn

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then

check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

LOQ 5-1 [What three issues have engaged developmental psychologists?](#)

LOQ 5-2 [What is the course of prenatal development, and how do teratogens affect that development?](#)

LOQ 5-3 [What are some newborn abilities, and how do researchers explore infants' mental abilities?](#)

TERMS AND CONCEPTS TO REMEMBER

Test yourself on these terms by trying to compose the definition before checking your answers.

[developmental psychology](#), p. 166

[zygote](#), p. 168

[embryo](#), p. 168

[fetus](#), p. 168

[teratogens](#), p. 171

[fetal alcohol syndrome \(FAS\)](#), p. 171

[habituation](#), p. 171

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The three major issues that interest developmental psychologists are nature/nurture, stability/change, and _____/_____.

Although development is lifelong, there is stability of personality over time. For example,

- a. most personality traits emerge in infancy and persist throughout life.
- b. temperament tends to remain stable throughout life.
- c. few people change significantly after adolescence.
- d. people tend to undergo greater personality changes as they age.

Body organs first begin to form and function during the period of the _____; within 6 months, during the period of the _____, organs are sufficiently functional to provide a good chance of surviving and thriving.

- a. zygote; embryo
- b. zygote; fetus
- c. embryo; fetus
- d. placenta; fetus

Chemicals that the placenta isn't able to screen out that can harm an embryo or fetus are called _____.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Infancy and Childhood

As a flower unfolds in accord with its genetic instructions, so do we.

Maturation—the orderly sequence of biological growth—decrees many of our commonalities. We stand before walking. We use nouns before adjectives. Severe deprivation or abuse can slow development, but genetic growth patterns are inborn. Maturation (nature) sets the basic course of development; experience (nurture) adjusts it. Genes and scenes interact.

maturation biological growth processes that enable orderly changes in behavior, relatively uninfluenced by experience.

Physical Development

LOQ 5-4 During infancy and childhood, how do the brain and motor skills develop?

Brain Development

In your mother's womb, your developing brain formed nerve cells at the explosive rate of nearly one-quarter million per minute. The developing brain cortex actually overproduces neurons, with the number peaking at 28 weeks (Rabinowicz et al., 1996, 1999).

From infancy on, brain and mind—neural hardware and cognitive software—develop together. On the day you were born, you had most of the brain cells you would ever have. However, your nervous system was immature: After birth, the branching neural networks that eventually enabled you to walk, talk, and remember had a wild growth spurt (**FIGURE 5.5**). This rapid development helps explain why infant brain size increases rapidly in the early days after birth (Holland et al., 2014). From ages 3 to 6, the most rapid growth was in your frontal lobes, which enable rational planning. During

those years, your brain required vast amounts of energy (Kuzawa et al., 2014). This energy-intensive process caused rapid progress in your ability to control your attention and behavior (Garon et al., 2008; Thompson-Schill et al., 2009).

FIGURE 5.5 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 5.5 Infant brain development

In humans, the brain is immature at birth. As the child matures, the neural networks grow increasingly complex.

The brain's association areas—those linked with thinking, memory, and language—were the last cortical areas to develop. As they did, your mental abilities surged (Chugani & Phelps, 1986; Thatcher et al., 1987). Fiber pathways supporting agility, language, and self-control proliferated into puberty. Under the influence of adrenal hormones, tens of billions of synapses formed and organized, while a use-it-or-lose-it *pruning* process shut down unused links (Paus et al., 1999; Thompson et al., 2000).

PA Archive/The Image Works

The baby experiment

Technology helps researchers understand infant brains, and what happens when development goes awry (Geddes, 2015).

Motor Development

The developing brain enables physical coordination. Skills emerge as infants exercise their maturing muscles and nervous system. With occasional exceptions, the sequence of physical (motor) development is universal. Babies roll over before they sit unsupported, and they usually crawl before they walk. These behaviors reflect not imitation but a maturing nervous system; blind children, too, crawl before they walk.

Genes guide motor development. In the United States, 25 percent of all babies walk by 11 months of age, 50 percent within a week after their first birthday, and 90 percent by age 15 months (Frankenburg et al., 1992). Identical twins typically begin walking on nearly the same day (Wilson, 1979). Maturation—including the rapid development of the cerebellum at the back of the brain—creates our readiness to learn walking at about age 1. The same is true for other physical skills, including bowel and bladder control. Before necessary muscular and neural maturation, neither pleading nor punishment will produce successful toilet training. You can't rush a child's first flush.

Physical development

Sit, crawl, walk, run—the sequence of these motor development milestones is the same the world around, though babies reach them at varying ages.

RETRIEVAL PRACTICE

RP-5 The biological growth process, called _____, explains why most children begin walking by about 12 to 15 months.

ANSWER: maturation

Still, nurture may amend what nature intends. In some regions of Africa, the Caribbean, and India, caregivers often massage and exercise babies, which can accelerate the process of learning to walk (Karasik et al., 2010). The recommended infant *back to sleep position* (putting babies to sleep on their backs to reduce crib-death risk) has been associated with somewhat later crawling but not with later walking (Davis et al., 1998; Lipsitt, 2003).

In the eight years following the 1994 launch of a U.S. Back to Sleep educational campaign, the number of infants sleeping on their stomach dropped from 70 to 11 percent—and sudden unexpected infant deaths fell significantly (Braiker, 2005).

"Someday we'll look back at this time in our lives and be unable to remember it."

Brain Maturation and Infant Memory

Can you recall your third birthday party? Studies suggest that we *consciously* recall little from before age 4. Mice and monkeys also forget their early life, as rapid neuron growth disrupts the circuits that stored old memories (Akers et al., 2014). But as children mature, this *infantile amnesia* wanes, and they become increasingly capable of remembering experiences, even for a year or more (Bauer & Larkina, 2014; Morris et al., 2010). The brain areas underlying memory, such as the hippocampus and frontal lobes, continue to mature during and after adolescence (Luby et al., 2016; Murty et al., 2016).

Despite *consciously* recalling little from our early years, our brain was processing and storing information. While finishing her doctoral work in psychology, Carolyn Rovee-Collier observed nonverbal infant memory in action. Her colicky 2-month-old, Benjamin, could be calmed by moving a crib mobile. Weary of hitting the mobile, she strung a cloth ribbon connecting the mobile to Benjamin's foot. Soon, he was kicking his foot to move the mobile. Thinking about her unintended home experiment, Rovee-

Collier realized that, contrary to popular opinion in the 1960s, babies can learn. To know for sure that her son wasn't just a whiz kid, she repeated the experiment with other infants (Rovee-Collier, 1989, 1999). Sure enough, they, too, soon kicked more when hitched to a mobile, both on the day of the experiment and the day after. If, however, she hitched them to a different mobile the next day, the infants showed no learning, indicating that they remembered the original mobile and recognized the difference. Moreover, when tethered to the familiar mobile a month later, they remembered the association and again began kicking ([FIGURE 5.6](#)).

FIGURE 5.6 Myers/DeWall, *Psychology*, 12e,

FIGURE 5.6 Infant at work

Babies only 3 months old learned that kicking moves a mobile, and they retained that learning for a month (Rovee-Collier, 1989, 1997).

Traces of forgotten childhood languages may also persist. One study tested English-speaking British adults who had no conscious memory of the Hindi or Zulu they had spoken as children. Yet, up to age 40, they could relearn subtle sound contrasts in these languages that other English speakers

could *not* learn (Bowers et al., 2009). Chinese adoptees living in Canada since age 1 process Chinese sounds as do native speakers, even if they have no conscious recollection of Chinese words (Pierce et al., 2014). Again, our two-track mind is at work: What the conscious mind does not know and cannot express in words, the nervous system and unconscious mind somehow remember.

Cognitive Development

LOQ 5-5 From the perspectives of Piaget, Vygotsky, and today's researchers, how does a child's mind develop?

Somewhere on your precarious journey “from egghood to personhood” (Broks, 2007), you became conscious. When was that? In search of the conscious thoughts of an infant—or, rather, a neural signal that marks early conscious awareness—one French research team flashed faces on a screen. At first, the faces appeared so briefly that even a typical adult could not consciously perceive them. Gradually, the presentation slowed until an adult brain-wave response signaled conscious awareness, about 300 milliseconds after an image appeared. With enough time to process the faces, 5-month-old infants displayed the same brain signature of visual awareness (Dehaene, 2014; Kouider et al., 2013).

Once conscious, how did your mind grow? Developmental psychologist Jean Piaget [pee-ah-ZHAY] spent his life searching for the answer. He studied children's **cognition**—all the mental activities associated with thinking, knowing, remembering, and communicating. His interest in children's cognitive development began in 1920, when he was in Paris developing questions for children's intelligence tests. While administering the tests, Piaget became intrigued by children's wrong answers, which were often strikingly similar among same-age children. Where others saw childish mistakes, Piaget saw intelligence at work. Such accidental discoveries are among the fruits of psychological science.

cognition all the mental activities associated with thinking, knowing, remembering, and communicating.

A half-century spent with children convinced Piaget that a child's mind is not a miniature model of an adult's. Thanks partly to his careful observations, we now understand that children reason differently than adults, in “wildly illogical ways” (Brainerd, 1996).

Piaget's studies led him to believe that a child's mind develops through a series of stages, in an upward march from the newborn's simple reflexes to the adult's abstract reasoning power. Thus, an 8-year-old can comprehend things a toddler cannot, such as the analogy that “getting an idea is like having a light turn on in your head.”

Piaget's core idea was that our intellectual progression reflects an unceasing struggle to make sense of our experiences. To this end, the maturing brain builds [schemas](#), concepts or mental molds into which we pour our experiences.

schema a concept or framework that organizes and interprets information.

Bill Anderson/Science Source

Jean Piaget (1896–1980)

“If we examine the intellectual development of the individual or of the whole of humanity, we shall find that the human spirit goes through a certain number of stages, each different from the other” (1930).

To explain how we use and adjust our schemas, Piaget proposed two more concepts. First, we **assimilate** new experiences—we interpret them in terms of our current understandings (schemas). Having a simple schema for *dog*, for example, a toddler may call all four-legged animals *dogs*. But as we interact with the world, we also adjust, or **accommodate**, our schemas to incorporate information provided by new experiences. Thus, the child soon learns that the original *dog* schema is too broad and accommodates by refining the category. By adulthood we have built countless schemas, ranging from *cats* and *dogs* to our concept of *love* (**FIGURE 5.7**).

assimilation interpreting our new experiences in terms of our existing schemas.

accommodation adapting our current understandings (schemas) to incorporate new information.

FIGURE 5.7 A changing marriage schema

A generation ago, most people had a schema of marriage as a union between a man and a woman. The Netherlands was the first country to change its marriage laws to accommodate same-sex marriage (in 2001). Today, more than 20 other countries have also legalized same-

sex marriage.

Piaget's Theory and Current Thinking

Piaget believed that children construct their understanding of the world while interacting with it. Their minds experience spurts of change, followed by greater stability as they move from one cognitive plateau to the next, each with distinctive characteristics that permit specific kinds of thinking. In Piaget's view, cognitive development consisted of four major stages—*sensorimotor*, *preoperational*, *concrete operational*, and *formal operational*.

SENSORIMOTOR STAGE In the [sensorimotor stage](#), from birth to nearly age 2, babies take in the world through their senses and actions—through looking, hearing, touching, mouthing, and grasping. As their hands and limbs begin to move, they learn to make things happen.

sensorimotor stage in Piaget's theory, the stage (from birth to nearly 2 years of age) during which infants know the world mostly in terms of their sensory impressions and motor activities.

Very young babies seem to live in the present: Out of sight is out of mind. In one test, Piaget showed an infant an appealing toy and then flopped his beret over it. Before the age of 6 months, the infant acted as if the toy ceased to exist. Young infants lack [object permanence](#)—the awareness that objects continue to exist even when not perceived. By 8 months, infants begin exhibiting memory for things no longer seen. If you hide a toy, the infant will momentarily look for it ([FIGURE 5.8](#)). Within another month or two, the infant will look for it even after being restrained for several seconds.

object permanence the awareness that things continue to exist even when not perceived.

FIGURE 5.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
© Doug Goodman/Science Source

FIGURE 5.8 Object permanence

Infants younger than 6 months seldom understand that things continue to exist when they are out of sight. But for this older infant, out of sight is definitely not out of mind.

So does object permanence in fact blossom suddenly at 8 months, much as tulips blossom in spring? Today's researchers believe object permanence unfolds gradually, and they see development as more continuous than Piaget did. Even young infants will at least momentarily look for a toy where they saw it hidden a second before (Wang et al., 2004).

Researchers also believe Piaget and his followers underestimated young children's competence. Young children think like little scientists. They test ideas, make causal inferences, and learn from statistical patterns (Gopnik et al., 2015). Consider these simple experiments:

- *Baby physics*: Like adults staring in disbelief at a magic trick (the “Whoa!” look), infants look longer at and explore impossible scenes—a car seeming to pass through a solid object, a ball stopping in midair, or an object violating object permanence by magically disappearing (Baillargeon, 2008; Shuwairi & Johnson, 2013; Stahl & Feigenson, 2015). Why do infants show this visual bias? Because impossible events violate infants' expectations (Baillargeon et al., 2016).
- *Baby math*: Karen Wynn (1992, 2000, 2008) showed 5-month-olds one or two objects ([FIGURE 5.9a](#)). Then she hid the objects behind a screen, and visibly removed or added one ([Figure 5.9d](#)). When she lifted the screen, the infants sometimes did a double take, staring longer when shown a wrong number of objects ([Figure 5.9f](#)). But were they just responding to a greater or smaller *mass* of objects, rather than a change in *number* (Feigenson et al., 2002)? Later experiments showed that babies' number sense extends to larger numbers, to ratios, and to such things as drumbeats and motions (Libertus & Brannon, 2009; McCrink & Wynn, 2004; Spelke

et al., 2013). If accustomed to a Daffy Duck puppet jumping three times on stage, they showed surprise if it jumped only twice.

FIGURE 5.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.9 Baby math

Shown a numerically impossible outcome, 5-month-old infants stare longer (Wynn, 1992).

“It is a rare privilege to watch the birth, growth, and first feeble struggles of a living human mind.”

Annie Sullivan, in Helen Keller’s *The Story of My Life*, 1903

Clearly, infants are smarter than Piaget appreciated. Even as babies, we had a lot on our minds.

PREOPERATIONAL STAGE Piaget believed that until about age 6 or 7, children are in a **preoperational stage**—able to represent things with words and images but too young to perform *mental operations* (such as imagining an action and mentally reversing it). For a 5-year-old, the milk that seems “too much” in a tall, narrow glass may become just right if poured into a short, wide glass. Focusing only on the height dimension, this child cannot perform the operation of mentally pouring the milk back. Before about age 6, said Piaget, children lack the concept of **conservation**—the principle that quantity remains the same despite changes in shape (**FIGURE 5.10**).

preoperational stage in Piaget’s theory, the stage (from about 2 to 6 or 7 years of age) during which a child learns to use language but does not yet comprehend the mental operations of concrete logic.

conservation the principle (which Piaget believed to be a part of concrete operational reasoning) that properties such as mass, volume, and number remain the same despite changes in the forms of objects.

FIGURE 5.10 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Bianca Moscatelli/Worth Publishers

FIGURE 5.10 Piaget's test of conservation

This visually focused preoperational child does not yet understand the principle of conservation. When the milk is poured into a tall, narrow glass, it suddenly seems like “more” than when it was in the shorter, wider glass. In another year or so, she will understand that the amount stays the same.

Pretend Play Symbolic thinking and *pretend play* appear at an earlier age than Piaget supposed. Judy DeLoache (1987) discovered this when she showed children a model of a room and hid a miniature stuffed dog behind its miniature couch. The 2½-year-olds easily remembered where to find the miniature toy, but they could not use the model to locate an actual stuffed dog behind a couch in a real room. Three-year-olds—only 6 months older—usually went right to the actual stuffed animal in the real room, showing they *could* think of the model as a symbol for the room. Although Piaget did not view the stage transitions as abrupt, he probably would have been surprised to see symbolic thinking at such an early age.

For quick video examples of children being tested for conservation, visit **Concept Practice: Piaget and Conservation**.

Egocentrism Piaget taught us that preschool children are **egocentric**: They have difficulty perceiving things from another's point of view. They are like the person who, when asked by someone across a river, “How do I get to the other side?” answered, “You are on the other side.” Asked to “show Mommy your picture,” 2-year-old Gabriella holds the picture up facing her own eyes. Three-year-old Gray makes himself “invisible” by putting his hands over his eyes, assuming that if he can't see his grandparents, they can't see him.

Children's conversations also reveal their egocentrism, as one young boy demonstrated (Phillips, 1969, [p. 61](#)):

egocentrism in Piaget's theory, the preoperational child's difficulty taking another's point of view.

"Do you have a brother?"

"Yes."

"What's his name?"

"Jim."

"Does Jim have a brother?"

"No."

Like Gabriella, TV-watching preschoolers who block your view of the TV assume that you see what they see. They simply have not yet developed the ability to take another's viewpoint. Even we adults may overestimate the extent to which others share our opinions, knowledge, and perspectives. We assume that something will be clear to others if it is clear to us, or that e-mail recipients will "hear" our "just kidding" intent (Epley et al., 2004; Kruger et al., 2005). Perhaps you can recall asking someone to guess a simple tune such as "Happy Birthday" as you clapped or tapped it out. With the tune in your head, it seemed so obvious! But you suffered the *egocentric curse of knowledge*, assuming that what was in your head was also in someone else's.

Theory of Mind When Little Red Riding Hood realized her "grandmother" was really a wolf, she swiftly revised her ideas about the creature's intentions and raced away. Preschoolers, although still egocentric, develop this ability to infer others' mental states when they begin forming a [theory of mind](#) (Premack & Woodruff, 1978).

theory of mind people's ideas about their own and others' mental states—about their feelings, perceptions, and thoughts, and the behaviors these might predict.

David Myers

Egocentrism in action

“Look, Granddaddy, a match!” So said my [DM’s] granddaughter, Allie, at age 4, when showing me two memory game cards with matching pictures—that faced her.

“The curse of knowledge is the single best explanation I know of why good people write bad prose. It simply doesn’t occur to the writer that her readers don’t know what she knows.”

Psychologist Steven Pinker, *The Sense of Style*, 2014

Infants as young as 7 months show some knowledge of others’ beliefs (Kovács et al., 2010). With time, the ability to take another’s perspective develops. They come to understand what made a playmate angry, when a sibling will share, and what might make a parent buy a toy. They begin to tease, empathize, and persuade. And when making decisions, they use their understanding of how their actions will make others feel (Repacholi et al., 2016). Children who have an advanced ability to understand others’ minds tend to be helpful and well-liked (Imuta et al., 2016; Slaughter et al., 2015).

Between about ages 3 and 4½, children come to realize that others may hold false beliefs (Callaghan et al., 2005; Rubio-Fernández & Geurtz, 2013; Sabbagh et al., 2006). Jennifer Jenkins and Janet Astington (1996) showed Canadian children a Band-Aid box and asked them what was inside. Expecting Band-Aids, the children were surprised to discover that the box actually contained pencils. Asked what a child who had never seen the box would think was inside, 3-year-olds typically answered “pencils.” By age 4 to

5, the children's theory of mind had leapt forward, and they anticipated their friends' false belief that the box would hold Band-Aids.

In a follow-up experiment, children viewed a doll named Sally leaving her ball in a red cupboard ([FIGURE 5.11](#)). Another doll, Anne, then moved the ball to a blue cupboard. Researchers then posed a question: When Sally returns, where will she look for the ball? Children with *autism spectrum disorder* had difficulty understanding that Sally's state of mind differed from their own—that Sally, not knowing the ball had been moved, would return to the red cupboard. They also have difficulty reflecting on their own mental states. They are, for example, less likely to use the personal pronouns *I* and *me*. Deaf children with hearing parents and minimal communication opportunities have had similar difficulty inferring others' states of mind (Peterson & Siegal, 1999).

FIGURE 5.11 Testing children's theory of mind

This simple problem illustrates how researchers explore children's presumptions about others' mental states. (Inspired by Baron-Cohen et al., 1985.)

CONCRETE OPERATIONAL STAGE By about age 7, said Piaget, children enter the [concrete operational stage](#). Given concrete (physical)

materials, they begin to grasp conservation. Understanding that change in form does not mean change in quantity, they can mentally pour milk back and forth between glasses of different shapes. They also enjoy jokes that use this new understanding:

concrete operational stage in Piaget's theory, the stage of cognitive development (from about 7 to 11 years of age) during which children gain the mental operations that enable them to think logically about concrete events.

Mr. Jones went into a restaurant and ordered a whole pizza for his dinner. When the waiter asked if he wanted it cut into 6 or 8 pieces, Mr. Jones said, "Oh, you'd better make it 6, I could never eat 8 pieces!" (McGhee, 1976)

Piaget believed that during the concrete operational stage, children become able to comprehend mathematical transformations and conservation. When my [DM's] daughter, Laura, was 6, I was astonished at her inability to reverse simple arithmetic. Asked, "What is 8 plus 4?" she required 5 seconds to compute "12," and another 5 seconds to then compute 12 minus 4. By age 8, she could answer a reversed question instantly.

FORMAL OPERATIONAL STAGE By age 12, our reasoning expands from the purely concrete (involving actual experience) to encompass abstract thinking (involving imagined realities and symbols). As children approach adolescence, said Piaget, they can ponder hypothetical propositions and deduce consequences: *If* this, *then* that. Systematic reasoning, what Piaget called **formal operational** thinking, is now within their grasp.

formal operational stage in Piaget's theory, the stage of cognitive development (normally beginning about age 12) during which people begin to think logically about abstract concepts.

Image Source/Vetta/Getty Images

Pretend play

Although full-blown logic and reasoning await adolescence, the rudiments of formal operational thinking begin earlier than Piaget realized. Consider this simple problem:

If John is in school, then Mary is in school. John is in school. What can you say about Mary?

Formal operational thinkers have no trouble answering correctly. But neither do most 7-year-olds (Suppes, 1982). [TABLE 5.1](#) summarizes the four stages in Piaget's theory.

TABLE 5.1

Piaget's Stages of Cognitive Development

Typical Age		
-------------	--	--

Range	Stage and Description	Key Milestones
<i>Birth to nearly 2 years</i>	<i>Sensorimotor</i> Experiencing the world through senses and actions (looking, hearing, touching, mouthing, and grasping)	<ul style="list-style-type: none"> • Object permanence • Stranger anxiety
<i>About 2 to 6 or 7 years</i>	<i>Preoperational</i> Representing things with words and images; using intuitive rather than logical reasoning	<ul style="list-style-type: none"> • Pretend play • Egocentrism
<i>About 7 to 11 years</i>	<i>Concrete operational</i> Thinking logically about concrete events; grasping concrete analogies and performing arithmetical operations	<ul style="list-style-type: none"> • Conservation • Mathematical transformations
<i>About 12 through adulthood</i>	<i>Formal operational</i> Reasoning abstractly	<ul style="list-style-type: none"> • Abstract logic • Potential for mature moral reasoning

An Alternative Viewpoint: Lev Vygotsky and the Social Child

As Piaget was forming his theory of cognitive development, Russian psychologist Lev Vygotsky was also studying how children think and learn. Where Piaget emphasized how the child's mind grows through interaction with the physical environment, Vygotsky emphasized how the child's mind grows through interaction with the *social* environment. If Piaget's child was a young scientist, Vygotsky's was a young apprentice. By giving children new words and mentoring them, parents, teachers, and other children provide a temporary [scaffold](#) from which children can step to higher levels of thinking (Renninger & Granott, 2005). Children learn best when their social environment presents them with something in the sweet spot between too easy and too difficult.

scaffold in Vygotsky's theory, a framework that offers children temporary support as they develop higher levels of thinking.

Language, an important ingredient of social mentoring, provides the building blocks for thinking, noted Vygotsky (who was born the same year as Piaget, but died prematurely of tuberculosis). By age 7, children increasingly think in words and use words to solve problems. They do this, Vygotsky said, by internalizing their culture's language and relying on inner speech (Fernyhough, 2008). Parents who say, "*No, no, Bevy!*" when pulling her hand away from a cup of hot coffee are giving their child a self-control tool. When Bevy later needs to resist temptation, she may likewise think, "*No, no, Bevy!*" Second graders who muttered to themselves while doing math problems grasped third-grade math better the following year (Berk, 1994). Whether out loud or inaudibly, talking to themselves helps children control their behavior and emotions and master new skills. (It helps adults, too. Adults who motivate themselves using self-talk—"You can do it!"—experience better performance [Kross et al., 2014].)

James V. Wertsch/Washington University

Lev Vygotsky (1896–1934)

Vygotsky, pictured here with his daughter, was a Russian developmental psychologist. He studied how a child's mind feeds on the language of social interaction.

RETRIEVAL PRACTICE

RP-6 Object permanence, pretend play, conservation, and abstract logic are developmental milestones for which of Piaget's stages, respectively?

ANSWER: Object permanence for the sensorimotor stage, pretend play for the preoperational stage, conservation for the concrete operational stage, and abstract logic for the formal operational stage.

RP-7 Match the correct cognitive developmental stage (a–d) to each developmental phenomenon (1–6).

- a. Sensorimotor
 - b. Preoperational
 - c. Concrete operational
 - d. Formal operational
1. Thinking about abstract concepts, such as “freedom.”
 2. Enjoying imaginary play (such as dress-up).
 3. Understanding that physical properties stay the same even when objects change form.
 4. Having the ability to reverse math operations.
 5. Understanding that something is not gone for good when it disappears from sight, as when Mom “disappears” behind the shower curtain.
 6. Having difficulty taking another's point of view (as when blocking someone's view of the TV).

ANSWER: 1. d, 2. b, 3. c, 4. c, 5. a, 6. b

Reflecting on Piaget's Theory

What remains of Piaget's ideas about the child's mind? Plenty—enough to merit his being singled out by *Time* magazine as one of the twentieth century's 20 most influential scientists and thinkers, and his being rated in a survey of British psychologists as the last century's greatest psychologist (*Psychologist*, 2003). Piaget identified significant cognitive milestones and stimulated worldwide interest in how the mind develops. His emphasis was less on the ages at which children typically reach specific milestones than on their sequence. Studies around the globe, from aboriginal Australia to Algeria to North America, have confirmed that human cognition unfolds basically in the sequence Piaget described (Lourenco & Machado, 1996; Segall et al., 1990).

"It's too late, Roger—they've seen us."

from cartoonbank.com. All Rights Reserved.

Roger has not outgrown his early childhood egocentrism.

However, today's researchers see development as more continuous than did Piaget. By detecting the beginnings of each type of thinking at earlier ages, they have revealed conceptual abilities Piaget missed. Moreover, they see formal logic as a smaller part of cognition than he did. Today, as part of our own cognitive development, we are adapting Piaget's ideas to accommodate new findings.

“Assessing the impact of Piaget on developmental psychology is like assessing the impact of Shakespeare on English literature.”

Developmental psychologist Harry Beilin (1992)

IMPLICATIONS FOR PARENTS AND TEACHERS Future parents and teachers remember: Young children are incapable of adult logic. Preschoolers who block one’s view of the TV simply have not learned to take another’s viewpoint. What seems simple and obvious to us—getting off a teeter-totter will cause a friend on the other end to crash—may be incomprehensible to a 3-year-old. Also remember that children are not passive receptacles waiting to be filled with knowledge. Better to build on what they already know, engaging them in concrete demonstrations and stimulating them to think for themselves. And, finally, accept children’s cognitive immaturity as adaptive. It is nature’s strategy for keeping children close to protective adults and providing time for learning and socialization (Bjorklund & Green, 1992).

“Childhood has its own way of seeing, thinking, and feeling, and there is nothing more foolish than the attempt to put ours in its place.”

Philosopher Jean-Jacques Rousseau, 1798

For a 7-minute synopsis of Piaget’s concepts, see the **Video: Cognitive Development**.

Autism Spectrum Disorder

LOQ 5-6 What is autism spectrum disorder?

Diagnoses of [autism spectrum disorder \(ASD\)](#), a disorder marked by social deficiencies and repetitive behaviors, have been increasing. Once believed to affect 1 in 2500 children (and referred to simply as *autism*), ASD now gets diagnosed in 1 in 68 American children by age 8. But the reported rates vary by place, with New Jersey having four times the reported prevalence of Alabama, while Britain’s children have a 1 in 100 rate, and South Korea’s 1 in 38 (CDC, 2014; Kim et al., 2011; NAS, 2011). The increase in ASD

diagnoses has been offset by a decrease in the number of children with a “cognitive disability” or “learning disability,” which suggests a relabeling of children’s disorders (Gernsbacher et al., 2005; Grinker, 2007; Shattuck, 2006).

autism spectrum disorder (ASD) a disorder that appears in childhood and is marked by significant deficiencies in communication and social interaction, and by rigidly fixated interests and repetitive behaviors.

Ozier Muhammad/The New York Times/Redux

Autism spectrum disorder

This speech-language pathologist is helping a boy with ASD learn to form sounds and words. ASD is marked by deficient social communication and difficulty grasping others’ states of mind.

The underlying source of ASD’s symptoms seems to be poor communication among brain regions that normally work together to let us take another’s viewpoint. From age 2 months on, as other children spend more and more time looking into others’ eyes, those who later develop ASD do so less and less (Jones & Klin, 2013). People with ASD are said to have an *impaired theory of mind* (Rajendran & Mitchell, 2007; Senju et al., 2009). Mind reading that most of us find intuitive (*Is that face conveying a smirk or*

a sneer?) is difficult for those with ASD. They have difficulty inferring and remembering others' thoughts and feelings, appreciating that playmates and parents might view things differently, and understanding that their teachers know more than they do (Boucher et al., 2012; Frith & Frith, 2001; Knutsen et al., 2015). Partly for such reasons, a national survey of parents and school staff reported that 46 percent of adolescents with ASD had suffered the taunts and torments of bullying—four times the 11 percent rate for other children (Sterzing et al., 2012). Children with ASD do make friends, but their peers often find such relationships emotionally unsatisfying (Mendelson et al., 2016).

ASD has differing levels of severity. About half of people with ASD experience a “fair” or even “good” outcome (Steinhausen et al., 2016). Some (those diagnosed with what used to be called *Asperger syndrome*) generally function at a high level. They have normal intelligence, often accompanied by exceptional skill or talent in a specific area, but deficient social and communication skills and a tendency to become distracted by irrelevant stimuli (Remington et al., 2009). Those at the spectrum's more severe end struggle to use language.

Biological factors, including genetic influences and abnormal brain development, contribute to ASD (Colvert et al., 2015; Makin, 2015; Tick et al., 2015). Studies suggest that the prenatal environment matters, especially when altered by maternal infection and inflammation, psychiatric drug use, or stress hormones (NIH, 2013; Wang, 2014). Childhood vaccinations do *not* contribute to ASD (Taylor et al., 2014). Based on a fraudulent 1998 study —“the most damaging medical hoax of the last 100 years” (Flaherty, 2011)—some parents were misled into thinking that the childhood MMR vaccine increased risk of ASD. The unfortunate result was a drop in vaccination rates and an increase in cases of measles and mumps. Some unvaccinated children suffer long-term harm or even death. Unvaccinated children also place those children too young to be fully vaccinated at risk.

Miller Mobley/August Image

“Autism” case number 1

In 1943, Donald Gray Triplett, an “odd” child with unusual gifts and social deficits, was the first person to receive the diagnosis of “autism.” (After a 2013 change in the diagnosis manual, his condition is now called *autism spectrum disorder*.) In 2016, at age 82, Triplett was still living in his family home and Mississippi town, where he often played golf (Atlas, 2016).

ASD afflicts about three boys for every girl (Loomes et al., 2017). Psychologist Simon Baron-Cohen (2010) believes this is because boys are often “systemizers.” They tend to understand things according to rules or laws, as in mathematical and mechanical systems. Girls, he contends, are naturally predisposed to be “empathizers.” They tend to excel at reading facial expressions and gestures (van Honk et al., 2011). And whether male or female, those with ASD are systemizers who have more difficulty reading facial expressions (Baron-Cohen et al., 2015).

Numerous studies verify biology’s influence. If one identical twin is diagnosed with ASD, the chances are 50 to 70 percent that the co-twin will be

as well (Tick et al., 2015). A younger genetic sibling of a child with ASD also is at a heightened risk (Sutcliffe, 2008). No one “autism gene” accounts for the disorder. Rather, many genes—with more than 400 identified so far—appear to contribute (Krishnan et al., 2016; Yuen et al., 2016). Random genetic mutations in sperm cells may also play a role. As men age, these mutations become more frequent, which may help explain why an over-40 man has a much higher risk of fathering a child with ASD than does a man under 30 (Reichenberg et al., 2007).

Researchers are also sleuthing ASD’s telltale signs in the brain’s structure. Several studies have revealed “underconnectivity”—fewer-than-normal fiber tracts connecting the front of the brain to the back (Picci et al., 2016). With underconnectivity, there is less of the whole-brain synchrony that, for example, integrates visual and emotional information.

Lisa Wiltse/Corbis News/Getty Images

Sharing more than appearance

Twins Johanna and Eva share a genetically influenced mild ASD.

Biology’s role in ASD also appears in the brain’s functioning. People without ASD often yawn after seeing others yawn. And as they view and imitate another’s smiling or frowning, they feel something of what the other is feeling. Not so among those with ASD, who are less imitative and show less activity in brain areas involved in mirroring others’ actions (Edwards, 2014; Yang & Hoffman, 2015). When people with ASD watch another person’s hand movements, for example, their brain displays less-than-normal mirroring activity (Oberman & Ramachandran, 2007; Théoret et al., 2005). Scientists are exploring and debating this idea that the brains of people with

ASD have “broken mirrors” (Gallese et al., 2011; Schulte-Rüther et al., 2016). And they are exploring whether treatment with oxytocin, the hormone that promotes social bonding, might improve social understanding in those with ASD (Gordon et al., 2013; Lange & McDougle, 2013).

Seeking to “systemize empathy,” Baron-Cohen and his Cambridge University colleagues (2007; Golan et al., 2010) collaborated with Britain’s National Autistic Society and a film production company. Knowing that television shows with vehicles have been popular among kids with ASD, they created animations with toy vehicle characters in a pretend boy’s bedroom, grafting emotion-conveying faces onto toy trams, trains, and tractors (**FIGURE 5.12**). After the boy leaves for school, the characters come to life and have experiences that lead them to display various emotions (see TheTransporters.com). The children were surprisingly able to generalize what they had learned to a new, real-life context. By the intervention’s end, their previously deficient ability to recognize emotions on real faces now equaled that of children without ASD.

FIGURE 5.12 Transported into a world of emotion

A research team at Cambridge University’s Autism Research Centre introduced children with ASD to emotions experienced and displayed by (a) toy vehicles and (b) human faces. Children matched the correct face with the story (“The neighbor’s dog has bitten people before. He is barking at Louise. Point to the face that shows how Louise is feeling”). (The graph shows data for two trials.)

RETRIEVAL PRACTICE

RP-8 What does *theory of mind* have to do with autism spectrum disorder?

ANSWER: Theory of mind focuses on our ability to understand our own and others' mental states. Those with autism spectrum disorder struggle with this ability.

Social Development

LOQ 5-7 How do parent-infant attachment bonds form?

From birth, most babies are social creatures, developing an intense attachment to their caregivers. Infants come to prefer familiar faces and voices, then to coo and gurgle when given a parent's attention. After about 8 months, soon after object permanence emerges and children become mobile, a curious thing happens: They develop [stranger anxiety](#). They may greet strangers by crying and reaching for familiar caregivers: "No! Don't leave me!" Children this age have schemas for familiar faces; when they cannot assimilate the new face into these remembered schemas, they become distressed (Kagan, 1984). Once again, we see an important principle: *The brain, mind, and social-emotional behavior develop together.*

stranger anxiety the fear of strangers that infants commonly display, beginning by about 8 months of age.

Origins of Attachment

One-year-olds typically cling tightly to a parent when they are frightened or expect separation. Reunited after being apart, they often shower the parent with smiles and hugs. This striking parent-infant [attachment](#) bond is a powerful survival impulse that keeps infants close to their caregivers. Infants normally become attached to those—typically their parents—who are

comfortable and familiar. For many years, psychologists reasoned that infants became attached to those who satisfied their need for nourishment. But an accidental finding overturned this explanation.

attachment an emotional tie with another person; shown in young children by their seeking closeness to their caregiver and showing distress on separation.

Christina Kennedy/Photo Edit

Stranger anxiety

A newly emerging ability to evaluate people as unfamiliar and possibly threatening helps protect babies 8 months and older.

BODY CONTACT During the 1950s, University of Wisconsin psychologists Harry Harlow and Margaret Harlow bred monkeys for their learning studies. To equalize experiences and to isolate any disease, they separated the infant monkeys from their mothers shortly after birth and raised them in individual cages, each including a cheesecloth baby blanket (Harlow et al., 1971). Then came a surprise: When their soft blankets were taken to be washed, the monkeys became distressed.

The Harlows recognized that this intense attachment to the blanket contradicted the idea that attachment derives from an association with nourishment. But how could they show this more convincingly? To pit the

drawing power of a food source against the contact comfort of the blanket, they created two artificial mothers. One was a bare wire cylinder with a wooden head and an attached feeding bottle, the other a cylinder wrapped with terry cloth.

When raised with both, the monkeys overwhelmingly preferred the comfy cloth mother ([FIGURE 5.13](#)). Like other infants clinging to their live mothers, the monkey babies would cling to their cloth mothers when anxious. When exploring their environment, they used her as a *secure base*, as if attached to her by an invisible elastic band that stretched only so far before pulling them back. Researchers soon learned that other qualities—rocking, warmth, and feeding—made the cloth mother even more appealing.

FIGURE 5.13 The Harlows' monkey mothers

Psychologists Harry Harlow and Margaret Harlow raised monkeys with two artificial mothers—one a bare wire cylinder with a wooden head and an attached feeding bottle, the other a cylinder with no bottle but covered with foam rubber and wrapped with terry cloth. The Harlows' discovery surprised many psychologists: The infants much preferred contact with the comfortable cloth mother, even while feeding from the wire nourishing mother.

Human infants, too, become attached to parents who are soft and warm and who rock, feed, and pat. Much parent-infant emotional communication occurs via touch, which can be either soothing (snuggles) or arousing (tickles) (Hertenstein et al., 2006). Indeed, when asked to describe the ideal mother, people across the globe agreed that she “shows affection by touching” (Mesman et al., 2015). Human attachment also consists of one person providing another with a secure base from which to explore and a safe haven when distressed. As we mature, our secure base and safe haven shift—from parents to peers and partners (Cassidy & Shaver, 1999). But at all ages we are social creatures. We gain strength when someone offers, by words and actions, a safe haven: “I will be here. I am interested in you. Come what may, I will support you” (Crowell & Waters, 1994).

Mark Peterson/Redux

Imprinting

Whooping cranes normally learn to migrate by following their parents. These cranes, hand-raised from eggs, have imprinted on a crane-costumed ultralight pilot, who then guided them to winter nesting grounds (Mooallem, 2009).

FAMILIARITY Contact is one key to attachment. Another is familiarity. In many animals, attachments based on familiarity form during a [critical period](#)—an optimal period when certain events must take place to facilitate proper development (Bornstein, 1989). For goslings, ducklings, or chicks, that

period falls in the hours shortly after hatching, when the first moving object they see is normally their mother. From then on, the young fowl follow her, and her alone.

critical period an optimal period early in the life of an organism when exposure to certain stimuli or experiences produces normal development.

Konrad Lorenz (1937) explored this rigid attachment process, called **imprinting**. He wondered: What would ducklings do if he was the first moving creature they observed? What they did was follow him around: Everywhere that Konrad went, the ducks were sure to go. Although baby birds imprint best to their own species, they also will imprint to a variety of moving objects—an animal of another species, a box on wheels, a bouncing ball (Colombo, 1982; Johnson, 1992). Once formed, this attachment is difficult to reverse.

imprinting the process by which certain animals form strong attachments during early life.

Children—unlike ducklings—do not imprint. However, they do become attached to what they've known. *Mere exposure* to people and things fosters fondness. Children like to reread the same books, rewatch the same movies, reenact family traditions. They prefer to eat familiar foods, live in the same familiar neighborhood, attend school with the same old friends. Familiarity is a safety signal. Familiarity breeds content.

For some people, a perceived relationship with God functions as do other attachments, by providing a secure base for exploration and a safe haven when threatened (Granqvist et al., 2010; Kirkpatrick, 1999).

RETRIEVAL PRACTICE

RP-9 What distinguishes imprinting from attachment?

ANSWER: Attachment is the normal process by which we form emotional ties with important others. Imprinting occurs only in certain animals that have a critical period very early in their development during which they must form their attachments, and they do so in an inflexible manner.

Attachment Differences

LOQ 5-8 How have psychologists studied attachment differences, and what have they learned?

What accounts for children's attachment differences? To answer this question, Mary Ainsworth (1979) designed the *strange situation* experiment. She observed mother-infant pairs at home during their first six months. Later she observed the 1-year-old infants in a strange situation (usually a laboratory playroom) with and without their mothers. Such research has shown that about 60 percent of infants and young children display *secure attachment* (Moulin et al., 2014). In their mother's presence they play comfortably, happily exploring their new environment. When she leaves, they become distressed; when she returns, they seek contact with her.

Other infants show *insecure attachment*, marked either by anxiety or avoidance of trusting relationships. These infants are less likely to explore their surroundings; they may even cling to their mother. When she leaves, they either cry loudly and remain upset or seem indifferent to her departure and return (Ainsworth, 1973, 1989; Kagan, 1995; van IJzendoorn & Kroonenberg, 1988).

Ainsworth and others found that sensitive, responsive mothers—those who noticed what their babies were doing and responded appropriately—had infants who exhibited secure attachment (De Wolff & van IJzendoorn, 1997). Insensitive, unresponsive mothers—mothers who attended to their babies when they felt like doing so but ignored them at other times—often had infants who were insecurely attached. The Harlows' monkey studies, with unresponsive artificial mothers, produced even more striking effects. When put in strange situations without their artificial mothers, the deprived infants

were terrified ([FIGURE 5.14](#)).

FIGURE 5.14 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Science Source

FIGURE 5.14 Social deprivation and fear

In the Harlows' experiments, monkeys raised with inanimate surrogate mothers were overwhelmed when placed in strange situations without that source of emotional security. (Today there is greater oversight and concern for animal welfare, which would regulate this type of study.)

Although remembered by some as the researcher who tortured helpless monkeys, Harry Harlow defended his methods: "Remember, for every mistreated monkey there exist a million mistreated children," he said, expressing the hope that his research would sensitize people to child abuse and neglect. "No one who knows Harry's work could ever argue that babies do fine without companionship, that a caring mother doesn't matter," noted Harlow biographer Deborah Blum (2011, pp. 292, 307). "And since we . . . didn't fully believe that before Harry Harlow came along, then perhaps we needed—just once—to be smacked really hard with that truth so that we could never again doubt."

So, caring parents matter. But is attachment style the *result* of parenting? Or is attachment style the result of genetically influenced *temperament*—a person's characteristic emotional reactivity and intensity? Twin and developmental studies reveal that heredity affects temperament, and temperament affects attachment style (Picardi et al., 2011; Raby et al., 2012). Shortly after birth, some babies are noticeably *difficult*—irritable, intense,

and unpredictable. Others are *easy*—cheerful, relaxed, and feeding and sleeping on predictable schedules (Chess & Thomas, 1987). By neglecting such inborn differences, the parenting studies, noted Judith Harris (1998), are like “comparing foxhounds reared in kennels with poodles reared in apartments.” So to separate nature and nurture, we would need to vary parenting while controlling temperament. (Pause and think: If you were the researcher, how might you do this?)

Dutch researcher Dymphna van den Boom’s (1994) solution was to randomly assign 100 temperamentally difficult 6- to 9-month-olds to either an experimental group, in which mothers received personal training in sensitive responding, or to a control group, in which they did not. At 12 months of age, 68 percent of the infants in the experimental group were securely attached, as were only 28 percent of the control-group infants. Other studies have confirmed that intervention programs can increase parental sensitivity and, to a lesser extent, infant attachment security (Bakermans-Kranenburg et al., 2003; Van Zeijl et al., 2006).

robertharding/Alamy

Parenting is for dads, too

Emperor penguin dads may lose half their body weight over the two months they spend keeping a precious egg warm during the harsh Antarctic winter. After mom returns from the sea, both parents take turns caring for and feeding the chick.

Brad Zweerink/ZUMA Press/Newscom

Full-time dad

Financial analyst Walter Cranford, shown here with his baby twins, is one of a growing number of stay-at-home dads. Cranford says the experience has made him appreciate how difficult the work can be: "Sometimes at work you can just unplug, but with this you've got to be going all the time."

As these examples indicate, researchers have more often studied mother care than father care. Infants who lack a caring mother are said to suffer "maternal deprivation"; those lacking a father's care merely experience "father absence." This reflects a wider attitude in which "fathering a child" has meant impregnating, and "mothering" has meant nurturing. But fathers are more than just mobile sperm banks. Across nearly 100 studies worldwide, a father's love and acceptance have been comparable with a mother's love in predicting their offspring's health and well-being (Rohner & Veneziano, 2001; see also [TABLE 5.2](#)). In one mammoth British study following 7259 children from birth to adulthood, those whose fathers were most involved in

parenting (through outings, reading to them, and taking an interest in their education) tended to achieve more in school, even after controlling for other factors such as parental education and family wealth (Flouri & Buchanan, 2004). Increasing nonmarital births and the greater instability of cohabiting versus married partnerships has, however, meant more father-absent families (Hymowitz et al., 2013).

TABLE 5.2
Dual Parenting Positives

<ul style="list-style-type: none"> • <i>Active dads are caregiving more.</i> Today's co-parenting fathers are more engaged, with a doubling in the weekly hours spent with their children, compared with fathers in 1965 (Livingston & Parker, 2011).
<ul style="list-style-type: none"> • <i>Couples that share housework and child care are happier in their relationships and less divorce prone</i> (Wilcox & Marquardt, 2011).
<ul style="list-style-type: none"> • <i>Dual parenting supports children.</i> After controlling for other factors, children average better life outcomes "if raised by both parents" (Taylor, 2014).
<ul style="list-style-type: none"> • <i>Parents' genders do not affect children's well-being.</i> The American Academy of Pediatrics (2013) reports that what matters is competent, secure, nurturing parents, regardless of their gender and sexual orientation. The American Sociological Association (2013) concurs: Decades of research confirm that parental stability and resources matter. "Whether a child is raised by same-sex or opposite-sex parents has no bearing on a child's well-being."

Children's anxiety over separation from parents peaks at around 13 months, then gradually declines ([FIGURE 5.15](#)). This happens whether they live with one parent or two, are cared for at home or in day care, live in North America, Guatemala, or the Kalahari Desert. Does this mean our need for and

love of others also fades away? Hardly. Our capacity for love grows, and our pleasure in touching and holding those we love never ceases.

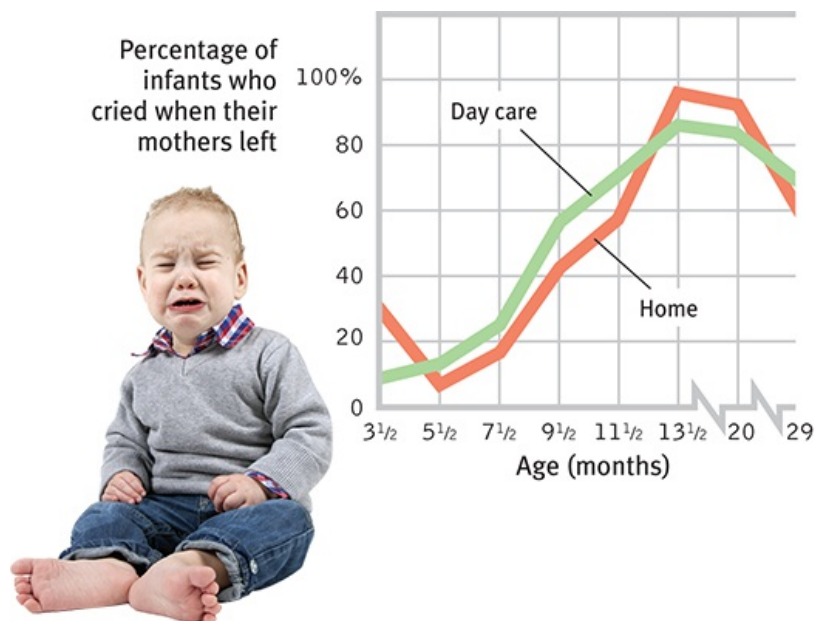

FIGURE 5.15 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Jouke van Keulen/Shutterstock

FIGURE 5.15 Infants' distress over separation from parents

In an experiment, infants were left by their mothers in an unfamiliar room. Regardless of whether the infant had experienced day care, the percentage who cried when the mother left peaked at about 13 months of age (Kagan, 1976).

ATTACHMENT STYLES AND LATER RELATIONSHIPS

Developmental psychologist Erik Erikson (1902–1994), working with his wife, Joan Erikson (1902–1997), believed that securely attached children approach life with a sense of **basic trust**—a sense that the world is predictable and reliable. He attributed basic trust not to environment or inborn temperament, but to early parenting. He theorized that infants blessed with sensitive, loving caregivers form a lifelong attitude of trust rather than fear.

basic trust according to Erik Erikson, a sense that the world is predictable and trustworthy; said to be formed during infancy by appropriate experiences with responsive caregivers.

Many researchers now believe that our early attachments form the foundation for our adult relationships and our comfort with affection and intimacy (Birnbaum et al., 2006; Fraley et al., 2013). People who report secure relationships with their parents tend to enjoy secure friendships (Gorrese & Ruggieri, 2012). Students leaving home to attend college or university—another kind of “strange situation”—tend to adjust well if closely attached to parents (Mattanah et al., 2011). Children with sensitive, responsive mothers tend to flourish socially and academically (Raby et al., 2014).

Feeling insecurely attached to others may take one of two main forms (Fraley et al., 2011). One is *anxious attachment*, in which people constantly crave acceptance but remain vigilant to signs of possible rejection. (Being sensitive to threat, anxiously attached people also tend to be skilled lie detectors and poker players [Ein-Dor & Perry, 2012, 2013].) The other is *avoidant attachment*, in which people experience discomfort getting close to others and use avoidant strategies to maintain distance from others. In romantic relationships, an anxious attachment style creates constant concern over rejection, leading people to cling to their partners. An avoidant style decreases commitment and increases conflict (DeWall et al., 2011; Overall et al., 2015).

“Out of the conflict between trust and mistrust, the infant develops hope, which is the earliest form of what gradually becomes faith in adults.”

Erik Erikson (1983)

“What is learned in the cradle, lasts to the grave.”

French proverb

To consider how your own attachment style may be affecting your current relationships, engage online with **Assess Your Strengths: What Is Your Attachment Style?**

Adult attachment styles can also affect relationships with one’s own

children. But say this for those (nearly half of all people) who exhibit wary, insecure attachments: Anxious or avoidant tendencies have helped our groups detect or escape dangers (Ein-Dor et al., 2010).

Deprivation of Attachment

LOQ 5-9 How does childhood neglect or abuse affect children's attachments?

If secure attachment nurtures social competence, what happens when circumstances prevent a child's forming any attachments? In all of psychology, there is no sadder research literature. Babies locked away at home under conditions of abuse or extreme neglect are often withdrawn, frightened, even speechless. The same is true of those raised in institutions without the stimulation and attention of a regular caregiver, as was tragically illustrated during the 1970s and 1980s in Romania. Having decided that economic growth for his impoverished country required more human capital, Nicolae Ceaușescu, Romania's Communist dictator, outlawed contraception, forbade abortion, and taxed families with fewer than five children. The birthrate skyrocketed. But unable to afford the children they had been coerced into having, many families had to leave them at government-run orphanages with untrained and overworked staff. Child-to-caregiver ratios often were 15 to 1, so the children were deprived of healthy attachments with at least one adult.

When tested after Ceaușescu's 1989 execution, these socially deprived children had lower intelligence scores, reduced brain development, abnormal stress responses, and quadruple the rate of attention-deficit/hyperactivity disorder (ADHD) found in children assigned to quality foster care settings (Bick et al., 2015; Kennedy et al., 2016; McLaughlin et al., 2015; Nelson et al., 2014). Dozens of other studies across 19 countries have confirmed that orphaned children tend to fare better on later intelligence tests if raised in family homes. This is especially so for those placed at an early age (van IJzendoorn et al., 2008).

Michael Carroll

The deprivation of attachment

In this 1980s Romanian orphanage, the 250 children between ages one and five outnumbered caregivers 15 to 1.

Most children growing up under adversity (such as the surviving children of the Holocaust and victims of childhood sexual abuse) are *resilient*; they withstand the trauma and become well-adjusted adults (Clancy, 2010; Helmreich, 1992; Masten, 2001). And hardship short of trauma often boosts mental toughness (Seery, 2011). Moreover, while enduring the hardship of growing up poor puts children at risk for some social pathologies, growing up rich puts them at risk for other problems. Affluent children are at elevated risk for substance abuse, eating disorders, anxiety, and depression (Lund & Dearing, 2012; Luthar et al., 2013). So when you face adversity, consider the possible silver lining. Your coping may strengthen your resilience—your tendency to bounce back and go on to lead a better life.

But many who experience enduring abuse don't bounce back so readily. The Harlows' monkeys raised in total isolation, without even an artificial mother, bore lifelong scars. As adults, when placed with other monkeys their age, they either cowered in fright or lashed out in aggression. When they reached sexual maturity, most were incapable of mating. If artificially impregnated, females often were neglectful, abusive, even murderous toward their first-born. Another primate experiment confirmed the abuse-breeds-abuse phenomenon: 9 of 16 female monkeys who had been abused by their mothers became abusive parents, as did *no* female raised by a nonabusive

mother (Maestripieri, 2005).

In humans, too, the unloved may become the unloving. Most abusive parents—and many condemned murderers—have reported being neglected or battered as children (Kempe & Kempe, 1978; Lewis et al., 1988). Some 30 percent of people who have been abused later abuse their children—a rate lower than that found in the primate study, but four times the U.S. national rate of child abuse (Dumont et al., 2007; Kaufman & Zigler, 1987).

Although most abused children do *not* later become violent criminals or abusive parents, extreme early trauma may nevertheless leave footprints on the brain (Romens et al., 2015; Teicher & Samson, 2016). Like battle-stressed soldiers, abused children's brains respond to angry faces with heightened activity in threat-detecting areas (McCrory et al., 2011). In conflict-plagued homes, even sleeping infants' brains show heightened reactivity to hearing angry speech (Graham et al., 2013). As adults, these children exhibit stronger startle responses (Jovanovic et al., 2009). If repeatedly threatened and attacked while young, normally placid golden hamsters grow up to be cowards when caged with same-sized hamsters, or bullies when caged with weaker ones (Ferris, 1996). Such animals show changes in the brain chemical serotonin, which calms aggressive impulses. A similarly sluggish serotonin response has been found in abused children who become aggressive teens and adults. By sensitizing the stress response system, early stress can permanently heighten reactions to later stress and increase stress-related disease (Fagundes & Way, 2014; van Zuiden et al., 2012; Wei et al., 2012). Child abuse, as we noted in [Chapter 4](#), can also leave *epigenetic* marks—chemical tags—that can alter normal gene expression.

Such findings help explain why young children who have survived severe or prolonged physical abuse, childhood sexual abuse, bullying, or wartime atrocities are at increased risk for health problems, psychological disorders, substance abuse, and criminality (Lereya et al., 2015; Trickett et al., 2011; Whitelock et al., 2013; Wolke et al., 2013). In one national study of 43,093 adults, 8 percent reported experiencing physical abuse at least fairly often before age 18 (Sugaya et al., 2012). Among these, 84 percent had experienced at least one psychiatric disorder. Moreover, the greater the abuse, the greater the odds of anxiety, depression, substance use disorder, and attempted suicide. Abuse victims are at considerable risk for depression if they carry a gene variation that spurs stress-hormone production (Bradley et

al., 2008). As we will see again and again, behavior and emotion arise from a particular environment interacting with particular genes.

“Stress can set off a ripple of hormonal changes that permanently wire a child’s brain to cope with a malevolent world.”

Abuse researcher Martin Teicher (2002)

We adults also suffer when our attachment bonds are severed. Whether through death or separation, a break produces a predictable sequence. Agitated preoccupation with the lost partner is followed by deep sadness and, eventually, the beginnings of emotional detachment and a return to normal living (Hazan & Shaver, 1994). Newly separated couples who have long ago ceased feeling affection are sometimes surprised at their desire to be near the former partner. Detaching is a process, not an event.

Developing a Self-Concept

LOQ 5-10 How do children’s self-concepts develop?

Infancy’s major social achievement is attachment. *Childhood’s* major social achievement is a positive sense of self. By the end of childhood, at about age 12, most children have developed a **self-concept**—an understanding and assessment of who they are. Parents often wonder when and how this sense of self develops. “Is my baby girl aware of herself—does she know she is a person distinct from everyone else?”

self-concept all our thoughts and feelings about ourselves, in answer to the question, “Who am I?”

Of course we cannot ask the baby directly, but we can again capitalize on what she can do—letting her *behavior* provide clues to the beginnings of her self-awareness. In 1877, biologist Charles Darwin offered one idea: Self-awareness begins when we recognize ourselves in a mirror. To see whether a child recognizes that the girl in the mirror is indeed herself, researchers

sneakily dabbed color on her nose. At about 6 months, children reach out to touch their mirror image as if it were another child (Courage & Howe, 2002; Damon & Hart, 1982, 1988, 1992). By 15 to 18 months, they begin to touch their own noses when they see the colored spot in the mirror (Butterworth, 1992; Gallup & Suarez, 1986). Apparently, 18-month-olds have a schema of how their face should look, and they wonder, “What is that spot doing on *my* face?”

By school age, children’s self-concept has blossomed into more detailed descriptions that include their gender, group memberships, psychological traits, and similarities and differences compared with other children (Newman & Ruble, 1988; Stipek, 1992). They come to see themselves as good and skillful in some ways but not others. They form a concept of which traits, ideally, they would like to have. By age 8 or 10, their self-image is quite stable.

Children’s views of themselves affect their actions. Children who form a positive self-concept are more confident, independent, optimistic, assertive, and sociable (Maccoby, 1980). So how can parents encourage a positive yet realistic self-concept?

Kate Nurre

Self-awareness

Mirror images fascinate infants from the age of about 6 months. Only at about 18 months, however, does the child recognize that the image in the mirror is “me.”

Parenting Styles

LOQ 5-11 What are the four main parenting styles?

Some parents spank, others reason. Some are strict, others are lax. Some show little affection, others liberally hug and kiss. How do parenting-style differences affect children?

The most heavily researched aspect of parenting has been how, and to what extent, parents seek to control their children. Parenting styles can be described as a combination of two traits: how *responsive* and how *demanding* parents are (Kakinami et al., 2015). Investigators have identified four parenting styles (Baumrind, 1966, 1967; Steinberg, 2001):

Authoritarian parents are *coercive*. They impose rules and expect obedience: “Don’t interrupt.” “Keep your room clean.” “Don’t stay out late or you’ll be grounded.” “Why? Because I said so.”

Permissive parents are *unrestraining*. They make few demands, set few limits, and use little punishment.

Negligent parents are *uninvolved*. They are neither demanding nor responsive. They are careless, inattentive, and do not seek to a close relationship with their children.

Authoritative parents are *confrontive*. They are both demanding and responsive. They exert control by setting rules, but, especially with older children, they encourage open discussion and allow exceptions.

For more on parenting styles and their associated outcomes, see Thinking Critically About: Parenting Styles.

LOQ 5-12 What outcomes are associated with each parenting style?

Thinking Critically About: Parenting Styles—

Too Hard, Too Soft, Too Uncaring, and Just Right?

Researchers have identified four parenting styles,¹ which have been associated with varying outcomes.

1 Authoritarian parents

Children with less social skill and self-esteem, and a brain that overreacts when they make mistakes²

2 Permissive parents

Children who are more aggressive and immature³

HOWEVER, Correlation ≠ Causation!

What other factors might explain this parenting-competence link? Children's traits may influence parenting. Parental warmth and control vary somewhat from child to child, even in the same family.⁶ Maybe socially mature, agreeable, easygoing children evoke greater trust and warmth from their parents? Twin studies have supported this possibility.⁷ Some underlying third factor may be at work. Perhaps, for example, competent parents and their competent children share genes that predispose social competence. Twin studies have also supported this possibility.⁸

3 Negligent parents

Children with poor academic and social outcomes⁴

4 Authoritative parents

Children with the highest self-esteem, self-reliance, self-regulation, and social competence⁵

1. Kakinami et al., 2015. 2. Meyer et al., 2015. 3. Luyckx et al., 2011. 4. Pinquart, 2015; Steinberg et al., 1994. 5. Baumrind, 1996, 2013; Buri et al., 1988; Coopersmith, 1967; Sulik et al., 2015. 6. Holden & Miller, 1999; Klahr & Burt, 2014. 7. Kendler, 1996. 8. South et al., 2008.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Parents who struggle with conflicting advice should remember that *all advice reflects the advice-giver's values*. For parents who prize unquestioning obedience, or whose children live in dangerous environments, an authoritarian style may have the desired effect. For those who value children's sociability and self-reliance, authoritative firm-but-open parenting is advisable.

The investment in raising a child buys many years of joy and love, but also of worry and irritation. Yet for most people who become parents, a child is one's legacy—one's personal investment in the human future. To paraphrase psychiatrist Carl Jung, we reach backward into our parents and forward into our children, and through their children into a future we will never see, but about which we must therefore care.

"You are the bows from which your children as living arrows are sent forth."

RETRIEVAL PRACTICE

RP-10 The four parenting styles may be described as “too hard, too soft, too uncaring, and just right.” Which parenting style goes with each of these descriptions, and how do children benefit from the “just right” style?

ANSWER: The authoritarian style would be described as too hard, the permissive style too soft, the negligent style too uncaring, and the authoritative style just right. Parents using the authoritative style tend to have children with high self-esteem, self-reliance, self-regulation, and social competence.

See the **Video: Correlational Studies** for a helpful tutorial animation about correlational research design.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Stroke a newborn's cheek and the infant will root for a nipple. This illustrates

- a. a reflex.
- b. nurture.
- c. a preference.
- d. continuity.

Between ages 3 and 6, the human brain experiences the greatest growth in the _____ lobes, which enable rational planning and aid memory.

Which of the following is true of motor-skill development?

- a. It is determined solely by genetic factors.
- b. The sequence, but not the timing, is universal.
- c. The timing, but not the sequence, is universal.
- d. It is determined solely by environmental factors.

Why can't we consciously recall how we learned to walk when we were infants?

Use Piaget's first three stages of cognitive development to explain why young children are not just miniature adults in the way they think.

Although Piaget's stage theory continues to inform our understanding of children's thinking, many researchers believe that

- a. Piaget's stages begin earlier and development is more continuous than he realized.
- b. children do not progress as rapidly as Piaget predicted.
- c. few children progress to the concrete operational stage.

d. there is no way of testing much of Piaget's theoretical work.

An 8-month-old infant who reacts to a new babysitter by crying and clinging to his father's shoulder is showing _____

_____.

In a series of experiments, the Harlows found that monkeys raised with artificial mothers tended, when afraid, to cling to their cloth mother, rather than to a wire mother holding the feeding bottle. Why was this finding important?

Adolescence

LOQ 5-13 How is *adolescence* defined, and how do physical changes affect developing teens?

Many psychologists once believed that childhood sets our traits. Today's developmental psychologists see development as lifelong. As this *life-span perspective* emerged, psychologists began to look at how maturation and experience shape us not only in infancy and childhood, but also in adolescence and beyond. **Adolescence**—the years spent morphing from child to adult—starts with the physical beginnings of sexual maturity and ends with the social achievement of independent adult status (which means that in some cultures, where teens are self-supporting, adolescence hardly exists).

adolescence the transition period from childhood to adulthood, extending from puberty to independence.

Copyright Andy Singer

At a five-year high school reunion, former best friends may be

surprised at their divergence; a decade or more later, they may have trouble sustaining a conversation.

In industrialized countries, what are the teen years like? In Leo Tolstoy's *Anna Karenina*, the teen years were “that blissful time when childhood is just coming to an end, and out of that vast circle, happy and gay, a path takes shape.” But another teenager, Anne Frank, writing in her diary while hiding from the Nazis, described tumultuous teen emotions:

My treatment varies so much. One day Anne is so sensible and is allowed to know everything; and the next day I hear that Anne is just a silly little goat who doesn't know anything at all and imagines that she's learned a wonderful lot from books. . . . Oh, so many things bubble up inside me as I lie in bed, having to put up with people I'm fed up with, who always misinterpret my intentions.

G. Stanley Hall (1904), one of the first psychologists to describe adolescence, believed that this tension between biological maturity and social dependence creates a period of “storm and stress.” It's a time when teens crave social acceptance, but often feel socially disconnected. Three in four U.S. friendships started in 7th grade dissolve by the time adolescents complete 8th grade (Hartl et al., 2015). Indeed, after age 30, many who grow up in independence-fostering Western cultures look back on their teenage years as a time they would not want to relive—a time when their peers' social approval was imperative, their sense of direction in life was in flux, and their feeling of alienation from their parents was deepest (Arnett, 1999; Macfarlane, 1964).

But for many, adolescence is a time of vitality without the cares of adulthood, a time of rewarding friendships, heightened idealism, and a growing sense of life's exciting possibilities.

How will you look back on your life 10 years from now? Are you making choices that someday you will recollect with satisfaction?

Physical Development

Adolescence begins with [puberty](#), the time when we mature sexually. Puberty

follows a surge of hormones, which may intensify moods and which trigger the bodily changes discussed in [Chapter 4](#).

puberty the period of sexual maturation, during which a person becomes capable of reproducing.

The timing of puberty. Just as in the earlier life stages, the *sequence* of physical changes in puberty (for example, breast buds and visible pubic hair before *menarche*—the first menstrual period) is far more predictable than their *timing*. Some girls start their growth spurt at 9, some boys as late as age 16. How do girls and boys experience early maturation?

For boys, early maturation has mixed effects. Boys who are stronger and more athletic during their early teen years tend to be more popular, self-assured, and independent, though also more at risk for alcohol use, delinquency, and premature sexual activity (Conley & Rudolph, 2009; Copeland et al., 2010; Lynne et al., 2007). For girls, early maturation can be a challenge (Mendle et al., 2007). If a young girl's body and hormone-fed feelings are out of sync with her emotional maturity and her friends' physical development and experiences, she may begin associating with older adolescents, suffer teasing or sexual harassment, or experience severe anxiety (Ge & Natsuaki, 2009; Weingarden & Renshaw, 2012).

Girls in various countries are developing breasts and reaching puberty earlier today than in the past, a phenomenon variously attributed to increased body fat, increased hormone-mimicking chemicals in the diet, and increased stress related to family disruption (Biro, F. M., et al., 2010, 2012; Ellis et al., 2012; Herman-Giddens, 2013). But the good news is that a secure child-mother attachment can provide a buffer against childhood stresses, including those related to early puberty (Sung et al., 2016). Remember: *Nature and nurture interact*.

The teenage brain. An adolescent's brain is still a work in progress. Until puberty, brain cells increase their connections, like trees growing more roots and branches. Then during adolescence comes a selective *pruning* of unused neurons and connections (Blakemore, 2008). What we don't use, we lose. It's rather like transportation engineers reducing congestion by moving traffic off the streets and onto the highways to get things moving more efficiently.

"Young man, go to your room and stay there until your cerebral cortex matures."

The New Yorker Collection 2006 by Barbara Smaller. From cartoonbank.com

As teens mature, their frontal lobes also continue to develop. The continuing growth of *myelin*, the fatty tissue that forms around axons and speeds neurotransmission, enables better communication with other brain regions (Whitaker et al., 2016). These developments bring improved judgment, impulse control, and long-term planning.

"I helped a so-called friend commit armed robbery and murder. . . . I was just 17 years old. . . . Been in prison for over 20 years . . . longer than I was ever free. . . . I am among the 300 plus "Juvenile Lifers" in Michigan prisons. I learned and matured a lot since my time incarcerated. I experience great remorse and regret over the tragedy that I ashamedly participated in. But I salvage this experience by learning and growing from it."

M. H., Michigan prison inmate, personal correspondence, 2015

Frontal lobe maturation nevertheless lags behind that of the emotional limbic system. Puberty's hormonal surge and limbic system development help explain teens' occasional impulsiveness, risky behaviors, and emotional storms—slamming doors and turning up the music (Casey et al., 2008; Casey and Caudle, 2013; Fuhrmann et al., 2015). No wonder younger teens (whose unfinished frontal lobes aren't yet fully equipped for making long-term plans

and curbing impulses) may succumb to the tobacco corporations. Teens actually don't underestimate the risks of smoking—or fast driving or unprotected sex. They just, when reasoning from their gut, weigh the benefits more heavily (Reyna & Farley, 2006; Steinberg, 2007, 2010). Teens find rewards more exciting than adults do. They seek thrills without a fully developed brake pedal controlling their impulses ([FIGURE 5.16](#)).

FIGURE 5.16 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.16 Impulse control lags reward seeking

Surveys of more than 7000 American 12- to 24-year-olds reveal that sensation seeking peaks in the mid-teens, with impulse control developing more slowly as frontal lobes mature. (National Longitudinal Study of Youth and Children and Young Adults survey data presented by Steinberg, 2013.)

So, when Junior drives recklessly and academically self-destructs, should his parents reassure themselves that “he can’t help it; his frontal cortex isn’t yet fully grown”? They can at least take hope: Brain changes underlie teens’ new self-consciousness about what others are thinking as well as their valuing of risky rewards (Barkley-Levenson & Galván, 2014; Somerville et al., 2013). And the brain with which Junior begins his teens differs from the brain with which he will end his teens. Unless he slows his brain

development with heavy drinking—leaving him prone to impulsivity and addiction—his frontal lobes will continue maturing until about age 25 (Crews et al., 2007; Giedd, 2015). They will also become better connected with the limbic system, enabling better emotion regulation (Cohen, A. O., et al., 2016; Steinberg, 2012).

"Be afraid to try new things!"

The New Yorker Collection Robert Leighton from cartoonbank.com. All Rights Reserved

In 2004, the American Psychological Association (APA) joined seven other medical and mental health associations in filing U.S. Supreme Court briefs, arguing against the death penalty for 16- and 17-year-olds. The briefs documented the teen brain's immaturity "in areas that bear upon adolescent decision making." Brain scans of young teens reveal that frontal lobe immaturity is most evident among juvenile offenders and drug users (Shannon et al., 2011; Whelan et al., 2012). Thus, teens are "less guilty by reason of adolescence," suggested psychologist Laurence Steinberg and law professor Elizabeth Scott (2003; Steinberg et al., 2009). In 2005, by a 5-to-4 margin, the Court concurred, declaring juvenile death penalties unconstitutional. In 2012, the APA offered similar arguments against sentencing juveniles to life without parole (Banville, 2012; Steinberg, 2013). Once again, the Court, by a narrow 5-to-4 vote, concurred.

Cognitive Development

LOQ 5-14 How did Piaget, Kohlberg, and later researchers describe

adolescent cognitive and moral development?

During the early teen years, reasoning is often self-focused. Adolescents may think their private experiences are unique, something parents just could not understand: “But, Mom, *you* don’t really know how it feels to be in love” (Elkind, 1978). Capable of thinking about their own thinking, and about other people’s thinking, they also begin imagining what others are thinking about *them*. (They might worry less if they understood their peers’ similar self-absorption.) Gradually, though, most begin to reason more abstractly.

“When the pilot told us to brace and grab our ankles, the first thing that went through my mind was that we must all look pretty stupid.”

Jeremiah Rawlings, age 12, after surviving a 1989 plane crash in Sioux City, Iowa

RICHARD B. LEVINE/Newscom; Kevork Djianseian/Getty Images

Demonstrating their reasoning ability

Although on opposite sides of the immigration policy debate, these teens are all demonstrating their ability to think logically about abstract topics. According to Piaget, they are in the final cognitive stage, formal operations.

Developing Reasoning Power

When adolescents achieve the intellectual summit that Jean Piaget called *formal operations*, they apply their new abstract reasoning tools to the world around them. They may think about what is ideally possible and compare that with the imperfect reality of their society, their parents, and themselves. They may debate human nature, good and evil, truth and justice. Their sense of what’s fair changes from simple equality to equity—to what’s proportional to

merit (Almås et al., 2010). Having left behind the concrete images of early childhood, they may search for spirituality and a deeper meaning of life (Boyatzis, 2012; Elkind, 1970). Reasoning hypothetically and deducing consequences also enables adolescents to detect inconsistencies and spot hypocrisy in others' reasoning. This can lead to heated debates with parents and silent vows never to lose sight of their own ideals (Peterson et al., 1986).

Developing Morality

Two crucial tasks of childhood and adolescence are discerning right from wrong and developing character—the psychological muscles for controlling impulses. Children learn to empathize with others, an ability that continues to develop in adolescence. To be a moral person is to *think* morally and *act* accordingly. Jean Piaget and Lawrence Kohlberg proposed that moral reasoning guides moral actions. A newer view builds on psychology's game-changing recognition that much of our functioning occurs not on the “high road” of deliberate, conscious thinking but on the “low road,” unconscious and automatic.

MORAL REASONING Piaget (1932) believed that children's moral judgments build on their cognitive development. Agreeing with Piaget, Lawrence Kohlberg (1981, 1984) sought to describe the development of *moral reasoning*, the thinking that occurs as we consider right and wrong. Kohlberg posed moral dilemmas (for example, whether a person should steal medicine to save a loved one's life) and asked children, adolescents, and adults whether the action was right or wrong. His analysis of their answers led him to propose three basic levels of moral thinking: preconventional, conventional, and postconventional ([TABLE 5.3](#)). Kohlberg claimed these levels form a moral ladder. As with all stage theories, the sequence is unvarying. We begin on the bottom rung and rise to varying heights, where we may place others' comfort above our own (Crockett et al., 2014). Infants recognize right and wrong, preferring moral over immoral action (Cowell & Decety, 2015). Preschoolers, typically identifying with their cultural group, conform to and enforce its moral norms (Haun et al., 2014; Schmidt & Tomasello, 2012). When those norms reward kind actions, preschoolers help others (Carragan & Dweck, 2014). Kohlberg's critics have noted that his postconventional stage is culturally limited, appearing mostly among people

from large societies that prize individualism (Barrett et al., 2016; Eckensberger, 1994; Miller & Bersoff, 1995).

TABLE 5.3

Kohlberg's Levels of Moral Thinking

<u>Level</u> (<u>approximate</u> <u>age</u>)	Focus	Example
Preconventional morality (before age 9)	Self-interest; obey rules to avoid punishment or gain concrete rewards.	"If you save your dying wife, you'll be a hero."
Conventional morality (early adolescence)	Uphold laws and rules to gain social approval or maintain social order.	"If you steal the drug for her, everyone will think you're a criminal."
Postconventional morality (adolescence and beyond)	Actions reflect belief in basic rights and self-defined ethical principles.	"People have a right to live."

MORAL INTUITION Psychologist Jonathan Haidt [pronounced HITE] (2002, 2012) believes that much of our morality is rooted in *moral intuitions*—"quick gut feelings, or affectively laden intuitions." According to this intuitionist view, the mind makes moral judgments in much the same way that it makes aesthetic judgments—quickly and automatically. Feelings of disgust or of elation trigger moral reasoning, says Haidt.

Adam Hunger/Reuters/Newscom

Moral reasoning

Some Staten Island, New York, residents faced a moral dilemma in 2012 when Superstorm Sandy caused disastrous flooding. Should they risk their lives to try to rescue family, friends, and neighbors in dangerously flooded areas? Their reasoning likely reflected different levels of moral thinking, even if they behaved similarly.

One woman recalled traveling through her snowy neighborhood with three young men as they passed “an elderly woman with a shovel in her driveway. . . . [O]ne of the guys . . . asked the driver to let him off there. . . . [M]y mouth dropped in shock as I realized that he was offering to shovel her walk for her.” Witnessing this unexpected goodness triggered elevation: “I felt like jumping out of the car and hugging this guy. I felt like singing and running, or skipping and laughing. I felt like saying nice things about people” (Haidt, 2000).

“Could human morality really be run by the moral emotions,” Haidt wonders, “while moral reasoning struts about pretending to be in control?” Consider the desire to punish. Laboratory games reveal that the desire to punish wrongdoing is mostly driven not by reason (such as an objective calculation that punishment deters crime) but rather by emotional reactions, such as moral outrage and the pleasure of revenge (Chester & DeWall, 2016; Darley, 2009). After the emotional fact, moral reasoning—our mind’s press secretary—aims to convince us and others of the logic of what we have

intuitively felt.

This intuitionist perspective on morality finds support in a study of moral paradoxes. Imagine seeing a runaway trolley headed for five people. All will certainly be killed unless you throw a switch that diverts the trolley onto another track, where it will kill one person. Should you throw the switch? Most say Yes. Kill one, save five.

Now imagine the same dilemma, except that your opportunity to save the five requires you to push a large stranger onto the tracks, where he will die as his body stops the trolley. The logic is the same—kill one, save five?—but most say No. Seeking to understand why, researchers used brain imaging to spy on people's neural responses as they contemplated such dilemmas. Only the body-pushing type of moral dilemma activated the brain's emotion areas (Greene et al., 2001). Thus, our moral judgments provide another example of the two-track mind—of dual processing (Feinberg et al., 2012). Moral reasoning, centered in one brain area, says throw the switch. Our intuitive moral emotions, rooted in other brain areas, override reason when saying *don't* push the man. Joshua Greene (2010) likens our moral cognition to a camera's settings. Usually, we rely on the automatic point-and-shoot. Yet sometimes we use reason to manually override the camera's automatic impulse.

"This might not be ethical. Is that a problem for anybody?"

The New Yorker Collection, 1987.
From cartoonbank.com

MORAL ACTION Our moral thinking and feeling surely affect our moral talk. But sometimes talk is cheap and emotions are fleeting. Morality involves *doing* the right thing, and what we do also depends on social

influences. As political theorist Hannah Arendt (1963) observed, many Nazi concentration camp guards during World War II were ordinary “moral” people who were corrupted by a powerfully evil situation.

Today’s character education programs tend to focus on the whole moral package—thinking, feeling, and *doing* the right thing. In service-learning programs, teens have tutored, cleaned up their neighborhoods, and assisted older adults. The result? The teens’ sense of competence and desire to serve has increased, their school absenteeism and dropout rates have dropped, and their violent behavior has diminished (Andersen, 1998; Heller, 2014; Piliavin, 2003). Moral action feeds moral attitudes.

A big part of moral development is the self-discipline needed to restrain one’s own impulses—to delay small gratifications now to enable bigger rewards later. One of psychology’s best-known experiments was sparked by Walter Mischel’s observations of his three preschool daughters’ “remarkable progression” in self-control (2014). He gave Stanford nursery school 4-year-olds a choice between one marshmallow now, or two marshmallows when he returned a few minutes later. The children who had the willpower to delay gratification went on to have higher college completion rates and incomes, and less often suffered addiction problems. Moreover, when a sample of Mischel’s marshmallow alums were retested on a new willpower test 40 years later, their differences persisted (Casey et al., 2011).

“It is a delightful harmony when doing and saying go together.”

Michel Eyquem de Montaigne (1533–1592)

Our capacity to *delay gratification*—to decline small rewards now for bigger rewards later—is basic to our future academic, vocational, and social success (Daly et al., 2015; Funder & Block, 1989; Sawyer et al., 2015). A preference for large-later rather than small-now rewards minimizes one’s risk of problem gambling, smoking, and delinquency (Callan et al., 2011; Ert et al., 2013; Lee et al., 2017). The moral of the story: Delaying gratification—living with one eye on the future—fosters flourishing.

RETRIEVAL PRACTICE

RP-11 According to Kohlberg, _____ morality focuses on

self-interest, _____ morality focuses on self-defined ethical principles, and _____ morality focuses on upholding laws and social rules.

ANSWER: preconventional; postconventional; conventional.

RP-12 How has Kohlberg's theory of moral reasoning been criticized?

ANSWER: Kohlberg's work reflected an individualist worldview, so his theory is less culturally universal than he supposed.

Social Development

LOQ 5-15 What are the social tasks and challenges of adolescence?

Theorist Erik Erikson (1963) contended that each stage of life has its own *psychosocial* task, a crisis that needs resolution. Young children wrestle with issues of *trust*, then *autonomy* (independence), then *initiative*. School-age children strive for *competence*, feeling able and productive. The adolescent's task is to synthesize past, present, and future possibilities into a clearer sense of self (**TABLE 5.4**). Adolescents wonder, "Who am I as an individual? What do I want to do with my life? What values should I live by? What do I believe in?" Erikson called this quest the adolescent's *search for identity*.

TABLE 5.4

Erikson's Stages of Psychosocial Development

Stage (approximate age)	Issue	Description of Task
<i>Infancy</i> (to 1 year)	Trust vs. mistrust	If needs are dependably met, infants develop a sense of basic trust.
<i>Toddlerhood</i> (1 to 3 years)	Autonomy vs. shame and doubt	Toddlers learn to exercise their will and do things for themselves, or they doubt their abilities.

<i>Preschool</i> (3 to 6 years)	Initiative vs. guilt	Preschoolers learn to initiate tasks and carry out plans, or they feel guilty about their efforts to be independent.
<i>Elementary school</i> (6 years to puberty)	Competence vs. inferiority	Children learn the pleasure of applying themselves to tasks, or they feel inferior.
<i>Adolescence</i> (teen years into 20s)	Identity vs. role confusion	Teenagers work at refining a sense of self by testing roles and then integrating them to form a single identity, or they become confused about who they are.
<i>Young adulthood</i> (20s to early 40s)	Intimacy vs. isolation	Young adults struggle to form close relationships and to gain the capacity for intimate love, or they feel socially isolated.
<i>Middle adulthood</i> (40s to 60s)	Generativity vs. stagnation	Middle-aged people discover a sense of contributing to the world, usually through family and work, or they may feel a lack of purpose.
<i>Late adulthood</i> (late 60s and up)	Integrity vs. despair	Reflecting on their lives, older adults may feel a sense of satisfaction or failure.

As sometimes happens in psychology, Erikson's interests were bred by his own life experience. As the son of a Jewish mother and a Danish Gentile father, Erikson was "doubly an outsider," reported Morton Hunt (1993, [p. 391](#)). He was "scorned as a Jew in school but mocked as a Gentile in the synagogue because of his blond hair and blue eyes." Such episodes fueled his interest in the adolescent struggle for identity.

"Somewhere between the ages of 10 and 13 (depending on how

hormone-enhanced their beef was), children entered adolescence, a.k.a. ‘the de-cutening.’”

Intimacy vs. isolation

Forming an Identity

To refine their sense of identity, adolescents in individualist cultures usually try out different “selves” in different situations. They may act out one self at

home, another with friends, and still another at school or online. If two situations overlap—as when a teenager brings new friends home—the discomfort can be considerable (Klimstra et al., 2015). The teen often wonders, “Which self should I be? Which is the real me?” The eventual resolution is a self-definition that unifies the various selves into a consistent and comfortable sense of who one is—an [identity](#).

identity our sense of self; according to Erikson, the adolescent’s task is to solidify a sense of self by testing and integrating various roles.

For both adolescents and adults, group identities are often formed by how we differ from those around us. When living in Britain, I [DM] become conscious of my Americanness. When spending time in Hong Kong, I [ND] become conscious of my minority White race. For international students, for those of a minority ethnic group, for gay and transgender people, or for people with a disability, a [social identity](#) often forms around their distinctiveness.

social identity the “we” aspect of our self-concept; the part of our answer to “Who am I?” that comes from our group memberships.

Erikson noticed that some adolescents forge their identity early, simply by adopting their parents’ values and expectations. Other adolescents may adopt the identity of a particular peer group—jocks, preps, geeks, band kids, debaters. Traditional, collectivist cultures teach adolescents who they are, rather than encouraging them to decide on their own. Bicultural adolescents form complex identities as they integrate multiple group memberships and their feelings about them (Marks et al., 2011).

“Self-consciousness, the recognition of a creature by itself as a ‘self,’ cannot exist except in contrast with an ‘other,’ a something which is not the self.”

C. S. Lewis, *The Problem of Pain*, 1940

Nine times out of ten, it's all about
peer pressure.

Most young people develop a sense of contentment with their lives. Which statement best describes you: “I would choose my life the way it is right now” or “I wish I were somebody else”? When American teens answered, 81 percent picked the first, and 19 percent the second (Lyons, 2004). Reflecting on their existence, 75 percent of American collegians say they “discuss religion/spirituality” with friends, “pray,” and agree that “we are all spiritual beings” and “search for meaning/purpose in life” (Astin et al., 2004; Bryant & Astin, 2008). This would not surprise Stanford psychologist William Damon and his colleagues (2003), who have contended that a key task of adolescence is to achieve a purpose—a desire to accomplish something personally meaningful that makes a difference to the world beyond oneself.

Several studies indicate that self-esteem typically falls during the early to mid-teen years, and, for girls, depression scores often increase. But then self-image rebounds during the late teens and twenties, and self-esteem gender differences become small (Zuckerman et al., 2016). Late adolescence is also a time when agreeableness and emotional stability scores increase (Klimstra et al., 2009).

For an interactive self-assessment of your own identity, see **PsychSim 6: Who Am I?**

Tristan Savatier/Getty Images; Wiklund, Juliana/Getty Images

Who shall I be today?

By varying the way they look, adolescents try out different “selves.” Although we eventually form a consistent and stable sense of identity, the self we present may change with the situation.

These are the years when many people in industrialized countries begin exploring new opportunities by attending college or working full time. Many college seniors have achieved a clearer identity and a more positive self-concept than they had as first-year students (Waterman, 1988). Those students who have achieved a clear sense of identity are less prone to alcohol misuse (Bishop et al., 2005).

Erikson contended that adolescent identity formation (which continues into adulthood) is followed in young adulthood by a developing capacity for [intimacy](#), the ability to form emotionally close relationships. When Mihaly Csikszentmihalyi [chick-SENT-me-hi] and Jeremy Hunter (2003) used a beeper to sample the daily experiences of American teens, they found them unhappiest when alone and happiest when with friends. Romantic relationships, which tend to be emotionally intense, are reported by some two in three North American 17-year-olds, but fewer in collectivist countries such as China (Collins et al., 2009; Li et al., 2010). Those who enjoy high-quality (intimate, supportive) relationships with family and friends tend also to enjoy similarly high-quality romantic relationships in adolescence, which set the stage for healthy adult relationships. Such relationships are, for most of us, a source of great pleasure. As Aristotle long ago recognized, we humans are “the social animal.” Relationships matter.

intimacy in Erikson's theory, the ability to form close, loving relationships; a primary developmental task in young adulthood.

Parent and Peer Relationships

LOQ 5-16 How do parents and peers influence adolescents?

As adolescents in Western cultures seek to form their own identities, they begin to pull away from their parents (Shanahan et al., 2007). The preschooler who can't be close enough to her mother, who loves to touch and cling to her, becomes the 14-year-old who wouldn't be caught dead holding hands with Mom. The transition occurs gradually (**FIGURE 5.17**). By adolescence, parent-child arguments occur more often, usually over mundane things—household chores, bedtime, homework (Tesser et al., 1989). Conflict during the transition to adolescence tends to be greater with first-born than with second-born children, and greater with mothers than with fathers (Burk et al., 2009; Shanahan et al., 2007).

FIGURE 5.17 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 5.17 The changing parent-child relationship

In a large national study of Canadian families, the typically close, warm relationships between children and their parents loosened as they became teens (Pepler & Craig, 2012.)

For a minority of parents and their adolescents, differences lead to real

splits and great stress (Steinberg & Morris, 2001). But most disagreements are at the level of harmless bickering. With sons, the issues often are behavior problems, such as acting out or hygiene; for daughters, the issues commonly involve relationships, such as dating and friendships (Schlomer et al., 2011). Most adolescents—6000 of them surveyed in 10 countries, from Australia to Bangladesh to Turkey—have said they like their parents (Offer et al., 1988). “We usually get along but . . .,” adolescents often reported (Galambos, 1992; Steinberg, 1987).

Positive parent-teen relations and positive peer relations often go hand in hand. High school girls who had the most affectionate relationships with their mothers tended also to enjoy the most intimate friendships with girlfriends (Gold & Yanof, 1985). And teens who felt close to their parents have tended to be healthy and happy and to do well in school (Resnick et al., 1997). Of course, we can state this correlation the other way: Misbehaving teens are more likely to have tense relationships with parents and other adults.

Adolescence is typically a time of diminishing parental influence and growing peer influence. Asked in a survey if they had “ever had a serious talk” with their child about illegal drugs, 85 percent of American parents answered *Yes*. But if the parents had indeed given this earnest advice, many teens had apparently tuned it out: Only 45 percent could recall such a talk (Morin & Brossard, 1997).

“She says she’s someone from your past who gave birth to you, and raised you, and sacrificed everything so you could have whatever you wanted.”

David Sipress

As we noted in [Chapter 4](#), heredity does much of the heavy lifting in forming individual temperament and personality differences, and peer influences do much of the rest. When with peers, teens discount the future and focus more on immediate rewards (O'Brien et al., 2011). Most teens are herd animals. They talk, dress, and act more like their peers than their parents. What their friends are, they often become, and what “everybody’s doing,” they often do. Teens’ social media use illustrates the power of peer influence. Compared to photos with few likes, teens prefer photos with many other likes—even photos of risky behaviors such as marijuana smoking. Moreover, when viewing many-liked photos, teens’ brains become more active in areas associated with reward processing and imitation (Sherman et al., 2016). Liking and doing what everybody else likes and does feels good.

Part of what everybody’s doing is networking—a lot. U.S. teens typically send 30 text messages daily and average 145 Facebook friends (Lenhart, 2015b). They tweet, post videos to Snapchat, and share pictures on Instagram. Online communication stimulates intimate self-disclosure—both for better (support groups) and for worse (online predators and extremist groups) (Subrahmanyam & Greenfield, 2008; Valkenburg & Peter, 2009; Wilson et al., 2012). A Facebook study of English-language users revealed that it took parent users and their children 371 days, on average, to “friend” each other (Burke et al., 2013).

"I'm fourteen, Mom, I don't do hugs."

The New Yorker Collection, David Sipress/
from cartoonbank.com. All Rights Reserved.

Both online and in real life, for those who feel excluded and bullied by their peers, the pain is acute. Most excluded “students suffer in silence. . . . A small number act out in violent ways against their classmates” (Aronson, 2001). The pain of exclusion also persists. In one large study, those who were bullied as children showed poorer physical health and greater psychological distress 40 years later (Takizawa et al., 2014).

So, for adolescents, peer approval matters. Yet in other ways, parental approval matters, too. Teens have seen their parents as influential in shaping their religious faith and in thinking about college and career choices (*Emerging Trends*, 1997). Most adolescents identify with their parents’ political views (Ojeda & Hatemi, 2015).

Emerging Adulthood

LOQ 5-17 What is emerging adulthood?

In the Western world, adolescence now roughly corresponds to the teen years. At earlier times, and in other parts of the world today, this slice of life has been much smaller (Baumeister & Tice, 1986). Shortly after sexual maturity, young people would assume adult responsibilities and status. The event might be celebrated with an elaborate initiation—a public rite of passage. The new adult would then work, marry, and have children.

“First, I did things for my parents’ approval, then I did things for my parents’ disapproval, and now I don’t know why I do things.”

Barbara Smaller/Funny Times

When schooling became compulsory in many Western countries,

independence was put on hold until after graduation. Adolescents are now taking more time to establish themselves as adults. In the United States, for example, the average age at first marriage has increased more than 5 years since 1960, to 29 for men, and 27 for women. In 1960, three in four women and two in three men had, by age 30, finished school, left home, become financially independent, married, and had a child. Today, fewer than half of 30-year-old women and one-third of men have met these five milestones (Henig, 2010).

Together, later independence and earlier sexual maturity have widened the once-brief interlude between biological maturity and social independence (**FIGURE 5.18**). In prosperous communities, the time from 18 to the mid-twenties is an increasingly not-yet-settled phase of life, now often called **emerging adulthood** (Arnett, 2006, 2007; Reitzle, 2006). No longer adolescents, these emerging adults, having not yet assumed full adult responsibilities and independence, feel “in between.” After high school, those who enter the job market or go to college may be managing their own time and priorities. Yet they may be doing so from their parents’ home, unable to afford their own place and perhaps still emotionally dependent as well. Recognizing today’s more gradually emerging adulthood, the U.S. government now allows dependent children up to age 26 to remain on their parents’ health insurance (Cohen, 2010).

FIGURE 5.18 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.18 The transition to adulthood is being stretched from both ends

In the 1890s, the average interval between a woman’s first menstrual period and marriage, which typically marked a transition to adulthood, was about 7 years. By 2006 in industrialized countries, that gap had

widened to about 14 years (Finer & Philbin, 2014; Guttmacher Institute, 1994). Although many adults are unmarried, later marriage combines with prolonged education and earlier menarche to help stretch out the transition to adulthood.

emerging adulthood a period from about age 18 to the mid-twenties, when many in Western cultures are no longer adolescents but have not yet achieved full independence as adults.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Adolescence is marked by the onset of

- a. an identity crisis.
- b. puberty.
- c. separation anxiety.
- d. parent-child conflict.

According to Piaget, a person who can think logically about abstractions is in the _____ stage.

In Erikson's stages, the primary task during adolescence is

- a. attaining formal operations.
- b. forging an identity.
- c. developing a sense of intimacy with another person.
- d. living independent of parents.

Some developmental psychologists refer to the period that occurs in some Western cultures from age 18 to the mid-twenties and beyond (up to the time of full adult independence) as _____

_____.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  LearningCurve to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Adulthood

The unfolding of our lives continues across the life span. It is, however, more difficult to generalize about adulthood stages than about life's early years. If you know that James is a 1-year-old and Jamal is a 10-year-old, you could say a great deal about each child. Not so with adults who differ by a similar number of years. The boss may be 30 or 60; the marathon runner may be 20 or 50; the 19-year-old may be a parent who supports a child or a child who receives an allowance. Yet our life courses are in some ways similar. Physically, cognitively, and especially socially, we differ at age 50 from our 25-year-old selves. In the discussion that follows, we recognize these differences and use three terms: *early adulthood* (roughly twenties and thirties), *middle adulthood* (to age 65), and *late adulthood* (the years after 65). Within each of these stages, people will vary widely in physical, psychological, and social development.

How old does a person have to be before you think of him or her as old? Depends on who you ask. For 18- to 29-year-olds, 67 was old. For those 60 and over, old was 76 (Yankelovich Partners, 1995).

"I am still learning."

Michelangelo, 1560, at age 85

Physical Development

LOQ 5-18 What physical changes occur during middle and late adulthood?

Like the declining daylight after the summer solstice, our physical abilities—muscular strength, reaction time, sensory keenness, and cardiac output—all begin an almost imperceptible decline in our mid-twenties. Athletes are often the first to notice. Baseball players peak at about age 27—with 60 percent of

Most Valuable Player awardees since 1985 coming within 2 years of that age (Silver, 2012). But most of us—especially those of us whose daily lives do not require top physical performance—hardly perceive the early signs of decline.

Physical Changes in Middle Adulthood

Athletes over 40 know all too well that physical decline gradually accelerates. As a lifelong basketball player, I [DM] find myself increasingly not racing for that loose ball. But even diminished vigor is sufficient for normal activities. Moreover, during early and middle adulthood, physical vigor has less to do with age than with a person's health and exercise habits. Many physically fit 50-year-olds run four miles with ease, while sedentary 25-year-olds find themselves huffing and puffing up two flights of stairs.

Rick Doyle/Corbis Documentary/Getty Images

Adult abilities vary widely

In 2012, George Blair maintained his place in the record books as the world's oldest barefoot water skier. He is shown here in 2002 when

he first set the record, at age 87. (He died in 2013 at age 98.)

Aging also brings a gradual decline in fertility, especially for women. For a 35- to 39-year-old woman, the chance of getting pregnant after a single act of intercourse is only half that of a woman 19 to 26 (Dunson et al., 2002). Men experience a gradual decline in sperm count, testosterone level, and speed of erection and ejaculation. Women experience [menopause](#), as menstrual cycles end, usually within a few years of age 50. Some may experience distress, as do some men who experience declining virility and physical capacities. But most people age without such problems.

menopause the time of natural cessation of menstruation; also refers to the biological changes a woman experiences as her ability to reproduce declines.

With age, sexual activity lessens. Nearly 9 in 10 Americans in their late twenties reported having had vaginal intercourse in the past year, compared with 22 percent of women and 43 percent of men over 70 (Herbenick et al., 2010; Reece et al., 2010). Nevertheless, most men and women remain capable of satisfying sexual activity, and most express satisfaction with their sex life. This was true of 70 percent of Canadians surveyed (ages 40 to 64) and 75 percent of Finns (ages 65 to 74) (Kontula & Haavio-Mannila, 2009; Wright, 2006). In one survey, 75 percent of respondents reported being sexually active into their eighties (Schick et al., 2010). And in an American Association of Retired Persons sexuality survey, it was not until age 75 or older that most women and nearly half of men reported little sexual desire (DeLamater, 2012; DeLamater & Sill, 2005). Given good health and a willing partner, the flames of desire, though simmered down, live on.

“The things that stop you having sex with age are exactly the same as those that stop you riding a bicycle (bad health, thinking it looks silly, no bicycle).”

Alex Comfort, *The Joy of Sex*, 2002

Physical Changes in Late Adulthood

Is old age “more to be feared than death” (Juvenal, *The Satires*)? Or is life “most delightful when it is on the downward slope” (Seneca, *Epistulae ad Lucilium*)? What is it like to grow old?

“Happy fortieth. I’ll take the muscle tone in your upper arms, the girlish timbre of your voice, your amazing tolerance for caffeine, and your ability to digest french fries. The rest of you can stay.”

The New Yorker Collection, 1999 Tom Cheney
from cartoonbank.com

LIFE EXPECTANCY From 1950 to 2015, life expectancy at birth increased worldwide from 46.5 years to 71 years—and to 80 and beyond in twenty-nine countries (WHO, 2016b). What a gift—two decades more of life! In China, the United States, the United Kingdom, Canada, and Australia (to name some countries where students read this book), life expectancy has risen to 76, 79, 81, 82, and 82, respectively (WHO, 2016). This increasing life expectancy (humanity’s greatest achievement, say some) combines with decreasing birthrates: Older adults are a growing population segment, creating an increasing demand for hearing aids, retirement villages, and nursing homes. Today, 1 in 10 people worldwide are 60 or older. The United Nations (2015b) projects that number will triple to nearly 3 in 10 by 2100 (and to nearly 4 in 10 in Europe).

“I intend to live forever—so far, so good.”

Comedian Steven Wright

Throughout the life span, males are more prone to dying. Although 126

male embryos begin life for every 100 females, the sex ratio is down to 105 males for every 100 females at birth (Strickland, 1992). During the first year, male infants' death rates exceed females' by one-fourth. Worldwide, women outlive men by 4.7 years (WHO, 2016b). (Rather than marrying a man older than themselves, 20-year-old women who want a husband who shares their life expectancy should wait for the 16-year-old boys to mature.) By age 100, women outnumber men 5 to 1.

But few of us live to 100. Disease strikes. The body ages. Its cells stop reproducing. It becomes frail and vulnerable to tiny insults—hot weather, a fall, a mild infection—that at age 20 would have been trivial. Tips of chromosomes, called *telomeres*, wear down, much as the tip of a shoelace frays. This wear is accelerated by smoking, obesity, or stress. Breast-fed children have longer telomeres, while those who suffer frequent abuse or bullying exhibit the biological scars of shortened telomeres (Shalev et al., 2013). As telomeres shorten, aging cells may die without being replaced with perfect genetic replicas (Epel, 2009).

Pascal Parrot/Sygma/Sygma via Getty Images

World record for longevity?

French woman Jeanne Calment, the oldest human in history with authenticated age, died in 1998 at age 122. At age 100, she was still riding a bike. At age 114, she became the oldest film actor ever, by portraying herself in *Vincent and Me*.

Low stress and good health habits enable longevity, as does a positive spirit. Chronic anger and depression increase our risk of premature death.

Researchers have even observed an intriguing *death-deferral* phenomenon (Shimizu & Pelham, 2008). Across one 15-year period, 2000 to 3000 more Americans died on the two days after Christmas than on Christmas and the two days before. The death rate also increases when people reach their birthdays, and when they survive until after other milestones, like the first day of the new millennium.

Betsy Streeter/CartoonStock

SENSORY ABILITIES, STRENGTH, AND STAMINA Although physical decline begins in early adulthood, we are not usually acutely aware of it until later in life, when the stairs get steeper, the print gets smaller, and other people seem to mumble more. Visual sharpness diminishes, as does distance perception and adaptation to light-level changes. Muscle strength, reaction time, and stamina also diminish, as do smell, hearing, and touch. In Wales, teens' loitering around a convenience store has been discouraged by a device that emits an aversive high-pitched sound that almost no one over 30 can hear (Lyall, 2005).

With age, the eye's pupil shrinks and its lens becomes less transparent, reducing the amount of light reaching the retina. A 65-year-old retina receives only about one-third as much light as its 20-year-old counterpart (Kline & Schieber, 1985). Thus, to see as well as a 20-year-old when reading

or driving, a 65-year-old needs three times as much light—a reason for buying cars with untinted windshields. This also explains why older people sometimes ask younger people, “Don’t you need better light for reading?”

“For some reason, possibly to save ink, the restaurants had started printing their menus in letters the height of bacteria.”

Dave Barry, *Dave Barry Turns Fifty*, 1998

Most stairway falls taken by older people occur on the top step, precisely where the person typically descends from a window-lit hallway into the darker stairwell (Fozard & Popkin, 1978). Our knowledge of aging could be used to design environments that would reduce such accidents (National Research Council, 1990).

HEALTH As people age, they care less about what their bodies look like and more about how their bodies function. For those growing older, there is both bad and good news about health. The bad news: The body’s disease-fighting immune system weakens, making older adults more susceptible to life-threatening ailments such as cancer and pneumonia. The good news: Thanks partly to a lifetime’s accumulation of antibodies, people over 65 suffer fewer short-term ailments, such as common flu and cold viruses. One study found they were half as likely as 20-year-olds and one-fifth as likely as preschoolers to suffer upper respiratory flu each year (National Center for Health Statistics, 1990).

Nicole Bengiveno/The New York Times/Redux

Suiting up for old age

A long life is a gift. To reach old age, it takes good genes, a nurturing environment, and a little luck. New technology allows you to put yourself in your elders' shoes. In these special suits, younger people can hear, see, and move as if they were 85 years old.

THE AGING BRAIN Up to the teen years, we process information with greater and greater speed (Fry & Hale, 1996; Kail, 1991). But compared with teens and young adults, older people take a bit more time to react, to solve perceptual puzzles, even to remember names (Bashore et al., 1997; Verhaeghen & Salthouse, 1997). At video games, most 70-year-olds are no match for a 20-year-old. This processing lag can also have deadly consequences (Aichele et al., 2016). As **FIGURE 5.19** indicates, fatal accident rates per mile driven increase sharply after age 75. By age 85, they exceed the 16-year-old level. Older drivers appear to focus well on the road ahead, but attend less to other vehicles approaching from the side (Pollatsek et al., 2012). Nevertheless, because older people drive less, they account for fewer than 10 percent of crashes (Coughlin et al., 2004).

FIGURE 5.19 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.19 Age and driver fatalities

Slowing reactions contribute to increased accident risks among those 75 and older, and their greater fragility increases their risk of death when accidents happen (NHTSA, 2000). Would you favor driver exams based on performance, not age, to screen out those whose slow reactions or sensory impairments indicate accident risk?

Brain regions important to memory begin to atrophy during aging (Fraser et al., 2015; Ritchie et al., 2015). The blood-brain barrier also breaks down beginning in the hippocampus, which furthers cognitive decline (Montagne et al., 2015). No wonder older adults feel older after taking a memory test: It's

like “aging 5 years in 5 minutes,” joked one research team (Hughes et al., 2013). In early adulthood, a small, gradual net loss of brain cells begins, contributing by age 80 to a brain-weight reduction of 5 percent or so. Earlier, we noted that late-maturing frontal lobes, which help us override our undesirable urges, help account for teen impulsivity. Late in life, some of that impulsiveness often returns as those same frontal lobes begin to atrophy, seemingly explaining older people’s occasional blunt questions (“Have you put on weight?”) or inappropriate comments (von Hippel, 2007, 2015). But good news: There is still some *plasticity* in the aging brain, which partly compensates for what it loses by recruiting and reorganizing neural networks (Park & McDonough, 2013). During memory tasks, for example, the left frontal lobes are especially active in young adult brains, while older adult brains use both left and right frontal lobes.

EXERCISE AND AGING And more good news: Exercise slows aging, as shown in studies of identical twin pairs in which only one twin exercised (Iso-Markku et al., 2016; Rottensteiner et al., 2015). Active older adults tend to be mentally quick older adults. Physical exercise not only enhances muscles, bones, and energy and helps prevent obesity and heart disease, it maintains the telomeres that protect the chromosome ends and even appears to slow the progression of Alzheimer’s disease (Leslie, 2011; Loprinzi et al., 2015; Smith et al., 2014).

Exercise also stimulates brain cell development and neural connections, thanks perhaps to increased oxygen and nutrient flow (Erickson et al., 2013; Fleischman et al., 2015; Pereira et al., 2007). Sedentary older adults randomly assigned to aerobic exercise programs exhibit enhanced memory, sharpened judgment, and reduced risk of severe cognitive decline (Raji et al., 2016; Smith, 2016). In aging brains, exercise reduces brain shrinkage (Gow et al., 2012). It promotes neurogenesis (the birth of new nerve cells) in the hippocampus, a brain region important for memory (Erickson, 2009; Pereira et al., 2007). And it increases the cellular mitochondria that help power both muscles and brain cells (Steiner et al., 2011). We are more likely to rust from disuse than to wear out from overuse. Fit bodies support fit minds.

"I've been working out for six months, but all my gains have been in cognitive function."

Cognitive Development

Aging and Memory

LOQ 5-19 How does memory change with age?

Among the most intriguing developmental psychology questions is whether adult cognitive abilities, such as memory, intelligence, and creativity, parallel the gradually accelerating decline of physical abilities.

As we age, we remember some things well. Looking back in later life, adults asked to recall the one or two most important events over the last half-century tend to name events from their teens or twenties (Conway et al., 2005; Rubin et al., 1998). They also display this “reminiscence bump” when asked to name their all-time favorite music, movies, and athletes (Janssen et al., 2012). Whatever people experience around this time—the Vietnam war, the 9/11 terrorist attacks, the election of the first Black U.S. president—becomes pivotal (Pillemer, 1998; Schuman & Scott, 1989). Our teens and twenties hold so many memorable “firsts”—first kiss, first job, first day at college or university, first meeting our romantic partner’s parents.

Early adulthood is indeed a peak time for some types of learning and remembering. In one test of recall, people watched video clips as 14 strangers said their names, using a common format: “Hi, I’m Larry” (Crook & West,

1990). Then those strangers reappeared and gave additional details. For example, they said, “I’m from Philadelphia,” providing more visual *and* voice cues for remembering the person’s name. As [FIGURE 5.20](#) shows, after a second and third replay of the introductions, everyone remembered more names, but younger adults consistently surpassed older adults. How well older people remember depends in part on the task. In another experiment, when asked to *recognize* 24 words they had earlier tried to memorize, older adults showed no memory decline. When asked to *recall* that information without clues, however, the decline was greater ([FIGURE 5.21](#)).

FIGURE 5.21 Recall and recognition in adulthood

In this experiment, the ability to recall new information declined during early and middle adulthood, but the ability to recognize new information did not. (Data from Schonfield & Robertson, 1966.)

Teens and young adults surpass both young children and 70-year-olds at *prospective memory* (“Remember to . . .”) (Zimmerman & Meier, 2006). But older people’s prospective memory remains strong when events help trigger a memory (as when walking by a convenience store triggers “Pick up milk!”). Time-based tasks (“Client meeting at 3:00 p.m.”) and especially habitual tasks (“Take medications at 9:00 a.m., 2:00 p.m., and 6:00 p.m.”) can be challenging (Einstein & McDaniel, 1990; Einstein et al., 1995, 1998). To minimize such problems, older adults rely more on time management and reminder cues, such as notes to themselves (Henry et al., 2004). This might have helped John Basinger, who, at age 76, memorized all 12 volumes of John Milton’s epic poem *Paradise Lost* and became the subject of a psychology journal article (Seamon et al., 2010; Weir, 2010). A local paper scheduled an interview with Basinger, which he forgot to attend. Calling the reporter to apologize, he

noted the irony of forgetting his interview about memory!

In our capacity to learn and remember, as in other areas of development, we show individual differences. Younger adults vary in their abilities to learn and remember, but 70-year-olds vary much more. “Differences between the most and least able 70-year-olds become much greater than between the most and least able 50-year-olds,” reported Oxford researcher Patrick Rabbitt (2006). Some 70-year-olds perform below nearly all 20-year-olds; other 70-year-olds match or outdo the average 20-year-old.

No matter how quick or slow we are, remembering seems also to depend on the type of information we are trying to retrieve. If the information is meaningless—nonsense syllables or unimportant events—then the older we are, the more errors we are likely to make. If the information is *meaningful*, as was *Paradise Lost* for John Basinger, older people’s rich web of existing knowledge will help them to hold it. But they may take longer than younger adults to *produce* the words and things they know. Older adults also more often experience tip-of-the-tongue forgetting (Ossher et al., 2012). Quick-thinking game show winners have usually been young or middle-aged adults (Burke & Shafto, 2004).

Maintaining Mental Abilities

Psychologists who study the aging mind debate whether “brain fitness” computer-based training programs can build mental muscles and stave off cognitive decline. Our brain remains plastic throughout life (Gutchess, 2014). So, can exercising our brains on a “cognitive treadmill”—with memory, visual tracking, and problem-solving exercises—avert losing our minds? “At every point in life, the brain’s natural plasticity gives us the ability to improve . . . function,” said one neuroscientist-entrepreneur (Merzenich, 2007). One analysis of cognitive training programs showed that they consistently improved scores on tests related to their training (Simons et al., 2016).

Based on such findings, some computer game makers have been marketing daily brain-exercise programs for older adults. But other researchers, after reviewing all the available studies, advise caution (Melby-Lervåg et al., 2016). One team of experts reported “extensive evidence that brain-training interventions improve performance on the trained tasks, less

evidence that such interventions improve performance on closely related tasks, and little evidence that training enhances performance on distantly related tasks or that training improves everyday cognitive performance” (Simons et al., 2016, [p. 103](#)). As researcher Zach Hambrick (2014) explains, “Play a video game and you’ll get better at that video game, and maybe at very similar video games”—but not at driving a car or filling out your tax return.

In 2016, the maker of one prominent brain-training program, Lumosity, was fined \$2 million for deceiving customers about the program’s supposed benefits. “Lumosity preyed on consumers’ fears about age-related cognitive decline,” said the Federal Trade Commission’s Jessica Rich (FTC, 2016). “But Lumosity simply did not have the science to back up its ads.”

[Chapter 10](#) explores another dimension of cognitive development: intelligence. As we will see, [cross-sectional studies](#) (comparing people of different ages) and [longitudinal studies](#) (restudying the same people over time) have identified mental abilities that do and do not change as people age. Age is less a predictor of memory and intelligence than is proximity to death. Knowing whether someone is 8 months or 8 years from a natural death, regardless of age, gives a clue to that person’s mental ability. In the last three or four years of life and especially as death approaches, negative feelings and cognitive decline typically increase (Vogel et al., 2013; Wilson et al., 2007b). Researchers call this near-death drop *terminal decline* (Backman & MacDonald, 2006). Our goals also shift: We’re driven less to learn and more to connect socially (Carstensen, 2011).

cross-sectional study research that compares people of different ages at the same point in time.

longitudinal study research that follows and retests the same people over time.

See the **Video: Longitudinal and Cross-Sectional Studies** for a helpful tutorial animation.

“The sudden knowledge of the fragility of his life narrowed his focus and altered his desires. . . . It made him visit with his grandchildren more often, put in an extra trip to see his family in India, and tamp down new ventures.”

Neurocognitive Disorders and Alzheimer’s Disease

LOQ 5-20 How do neurocognitive disorders and Alzheimer’s disease affect cognitive ability?

Most people who live into their nineties do so with clear minds. Some, unfortunately, suffer substantial psychological decline that is *not* normal aging. Among older adults, hearing loss, and its associated social isolation, predicts risk of depression and accelerated mental decline (Lin et al., 2011a,b, 2013; Mick & Pichora-Fuller, 2016). Compared with people with good hearing, those with hearing loss show declines in memory, attention, and learning about three years earlier. A series of small strokes, a brain tumor, or alcohol use disorder can progressively damage the brain, causing that mental erosion we call a [neurocognitive disorder](#) (NCD, formerly called *dementia*). Heavy midlife smoking more than doubles later risk of the disorder (Rusanen et al., 2011). The feared brain ailment [Alzheimer’s disease](#) strikes 3 percent of the world’s population by age 75. Up to age 95, the incidence of mental disintegration doubles roughly every 5 years.

neurocognitive disorders (NCDs) acquired (not lifelong) disorders marked by cognitive deficits; often related to Alzheimer’s disease, brain injury or disease, or substance abuse. In older adults, neurocognitive disorders were formerly called *dementia*.

Alzheimer’s disease a neurocognitive disorder marked by neural plaques, often with onset after age 80, and entailing a progressive decline in memory

and other cognitive abilities.

Alzheimer's destroys even the brightest of minds. First memory deteriorates, then reasoning. (Occasionally forgetting where you laid the car keys is no cause for alarm; forgetting how to get home may suggest Alzheimer's.) Robert Sayre (1979) recalled his father shouting at his afflicted mother to "think harder," while his mother, confused, embarrassed, on the verge of tears, randomly searched the house for lost objects. As the disease runs its course, after 5 to 20 years, the person becomes emotionally flat, then disoriented and disinhibited, then incontinent, and finally mentally vacant—a sort of living death, a mere body stripped of its humanity.

Underlying the symptoms of Alzheimer's are a loss of brain cells and a deterioration of neurons that produce the neurotransmitter acetylcholine, which is vital to memory and thinking. An autopsy reveals two telltale abnormalities in these acetylcholine-producing neurons: shriveled protein filaments in the cell body, and clumps of a free-floating protein fragment that accumulate as plaque at neuron tips where synaptic communication normally occurs. Long before symptoms appear, new technologies can now test for the Alzheimer's susceptibility gene or check spinal fluid for the culprit protein fragments (De Meyer et al., 2010; Luciano et al., 2009). Such discoveries have stimulated a race to invent and test drugs that may forestall the disease, such as by reducing the activity of a memory-inhibiting neurotransmitter called GABA (Chen et al., 2014). The recent discovery of 21 associated genes may help (Lambert et al., 2013).

A diminishing sense of smell and slowed or wobbly walking may foretell Alzheimer's (Belluck, 2012; Wilson et al., 2007a). In people at risk for Alzheimer's, brain scans ([FIGURE 5.22](#)) have also revealed—before symptoms appear—the degeneration of critical brain cells and diminished activity in Alzheimer's-related brain areas (Apostolova et al., 2006; Johnson et al., 2006; Wu & Small, 2006). When people memorized words, scans also showed diffuse brain activity, as if more exertion was required to achieve the same performance (Bookheimer et al., 2000).

FIGURE 5.22 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Susan Bookheimer

FIGURE 5.22 Predicting Alzheimer's disease

During a memory test, MRI scans of the brains of people at risk for Alzheimer's (left) revealed more intense activity (yellow, followed by orange and red) when compared with normal brains (right). As brain scans and genetic tests make it possible to identify those likely to suffer Alzheimer's, would you want to be tested? At what age?

Alzheimer's is somewhat less common among those who keep their minds and bodies active, through activities like reading, attending educational lectures, and running or lifting weights (Agrigoroaei & Lachman, 2011). As with muscles, so with the brain: Those who use it less often lose it.

Social Development

LOQ 5-21 What themes and influences mark our social journey from early adulthood to death?

Many differences between younger and older adults are created by significant life events. A new job means new relationships, new expectations, and new demands. Marriage brings the joy of intimacy and the stress of merging two lives. The three years surrounding the birth of a child bring increased life satisfaction for most parents (Dyrdal & Lucas, 2011). The death of a loved one creates an irreplaceable loss. Do these adult life events shape a sequence of life changes?

Adulthood's Ages and Stages

As people enter their forties, they undergo a transition to middle adulthood, a time when they realize that life will soon be mostly behind instead of ahead

of them. Some psychologists have argued that for many the *midlife transition* is a crisis, a time of great struggle, regret, or even feeling struck down by life. The popular image of the midlife crisis—an early-forties man who forsakes his family for a younger romantic partner and a hot sports car—is more a myth than reality. Unhappiness, job dissatisfaction, marital dissatisfaction, divorce, anxiety, and suicide do *not* surge during the early forties (Hunter & Sundel, 1989; Mroczek & Kolarz, 1998). Divorce, for example, is most common among those in their twenties, suicide among those in their seventies and eighties. One study of emotional instability in nearly 10,000 men and women found “not the slightest evidence” that distress peaks anywhere in the midlife age range (McCrae & Costa, 1990).

For the 1 in 4 adults who report experiencing a life crisis, the trigger is not age, but a major event, such as illness, divorce, or job loss (Lachman, 2004). Some middle-aged adults describe themselves as a “sandwich generation,” simultaneously supporting their aging parents and their emerging adult children or grandchildren (Riley & Bowen, 2005).

Life events trigger transitions to new life stages at varying ages. The [social clock](#)—the definition of “the right time” to leave home, get a job, marry, have children, and retire—varies from era to era and culture to culture. The once-rigid sequence has loosened; the social clock still ticks, but people feel freer about being out of sync with it.

social clock the culturally preferred timing of social events such as marriage, parenthood, and retirement.

Even *chance events* can have lasting significance, by deflecting us down one road rather than another. Albert Bandura (1982, 2005) recalls the ironic true story of a book editor who came to one of Bandura’s lectures on the “Psychology of Chance Encounters and Life Paths”—and ended up marrying the woman who happened to sit next to him. The sequence that led to my [DM’s] authoring this book (which was not my idea) began with my being seated near, and getting to know, a distinguished colleague at an international conference. The road to my [ND’s] co-authoring this book began in a similarly unplanned manner: After stumbling on an article about my professional life, DM invited me to visit his college. There, we began a

conversation that resulted in our collaboration. Chance events can change our lives.

“The important events of a person’s life are the products of chains of highly improbable occurrences.”

Joseph Traub, “Traub’s Law,” 2003

Adulthood’s Commitments

Two basic aspects of our lives dominate adulthood. Erik Erikson called them *intimacy* (forming close relationships) and *generativity* (being productive and supporting future generations). Sigmund Freud (1935/1960) put this more simply: The healthy adult, he said, is one who can *love* and *work*.

LOVE We typically flirt, fall in love, and commit—one person at a time. “Pair-bonding is a trademark of the human animal,” observed anthropologist Helen Fisher (1993). From an evolutionary perspective, relatively monogamous pairing makes sense: Parents who cooperated to nurture their children to maturity were more likely to have their genes passed along to posterity than were parents who didn’t.

Blend Images/Alamy

Love

Intimacy, attachment, commitment—love by whatever name—is central to healthy and happy adulthood.

Adult bonds of love are most satisfying and enduring when marked by a similarity of interests and values, a sharing of emotional and material support, and intimate self-disclosure. There also appears to be “vow power.” Straight and gay relationships sealed with commitment more often endure (Balsam et al., 2008; Rosenfeld, 2014). Such bonds are especially likely to last when couples marry after age 20 and are well educated. Compared with their counterparts of 30 years ago, people in Western countries *are* better educated and marrying later (Wolfinger, 2015). These trends may help explain why the American divorce rate, which surged from 1960 to 1980, has since leveled off and even slightly declined in some areas (Schoen & Canudas-Romo, 2006). Canadian divorce rates since the 1980s have followed a similar pattern (Statistics Canada, 2011). Despite the drop in divorce, our standards have risen. We now hope not only for an enduring bond, but also for a mate who is a wage earner, caregiver, intimate friend, and warm and responsive lover

(Finkel, 2017).

Historically, couples have met at school, on the job, or through friends and family. Thanks to the Internet, many couples now meet online—as have nearly a quarter of heterosexual couples and some two-thirds of same-sex couples in one recent national survey ([FIGURE 5.23](#)).

FIGURE 5.23 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.23 The changing way Americans meet their partners

A national survey of 2452 straight couples and 462 gay and lesbian couples reveals the increasing role of the Internet. (Data from Rosenfeld, 2013; Rosenfeld & Thomas, 2012.)

Might test-driving life together minimize divorce risk? In Europe, Canada, and the United States, those who live together before marriage (and especially before engagement) have had *higher* rates of divorce and marital dysfunction than those who did not (Goodwin et al., 2010; Jose et al., 2010; Manning & Cohen, 2012; Stanley et al., 2010). Three factors contribute. First, those who live together tend to be initially less committed to the ideal of enduring marriage. Second, they may become even less marriage-supporting while living together. Third, it's more awkward to break up with a cohabiting partner than with a dating partner, leading some cohabiters to marry someone “they otherwise would have left behind” (Stanley & Rhoades, 2016a,b).

Although there is more variety in relationships today, the institution of marriage endures. Ninety-five percent of Americans have either married or want to (Newport & Wilke, 2013). In Western countries, people marry for

love. What counts as a “very important” reason to marry? Among Americans, 31 percent say financial stability, and 93 percent say love (Cohn, 2013). And marriage is a predictor of happiness, sexual satisfaction, income, and physical and mental health (Scott et al., 2010). National Opinion Research Center surveys of more than 50,000 heterosexual Americans between 1972 and 2014 reveal that 40 percent of married adults, though only 23 percent of unmarried adults, have reported being “very happy.” Lesbian couples, too, have reported greater well-being than those who are single (Peplau & Fingerhut, 2007; Wayment & Peplau, 1995). Moreover, neighborhoods with high marriage rates typically have low rates of social pathologies such as crime, delinquency, and emotional disorders among children (Myers & Scanzoni, 2005).

Relationships that last are not always devoid of conflict. Some couples fight but also shower each other with affection. Other couples never raise their voices yet also seldom praise each other or nuzzle. Both styles can last. After observing the interactions of 2000 couples, John Gottman (1994) reported one indicator of marital success: at least a five-to-one ratio of positive to negative interactions. Stable marriages provide five times more instances of smiling, touching, complimenting, and laughing than of sarcasm, criticism, and insults. So, if you want to predict which couples will stay together, don’t pay attention to how passionately they are in love. The pairs who make it are more often those who refrain from putting down their partners. To prevent a cancerous negativity, successful couples learn to fight fair (to state feelings without insulting) and to steer conflict away from chaos with comments like “I know it’s not your fault” or “I’ll just be quiet for a moment and listen.”

What do you think? Does marriage correlate with happiness because marital support and intimacy breed happiness, because happy people more often marry and stay married, or both?

Often, love bears children. For most people, this most enduring of life changes is a happy event—one that adds meaning, joy, and occasional stress (S. K. Nelson et al., 2013; Witters, 2014). “I feel an overwhelming love for my children unlike anything I feel for anyone else,” said 93 percent of American mothers in a national survey (Erickson & Aird, 2005). Many

fathers feel the same. A few weeks after the birth of my first child I [DM] was suddenly struck by a realization: “So *this* is how my parents felt about me!”

“Our love for children is so unlike any other human emotion. I fell in love with my babies so quickly and profoundly, almost completely independently of their particular qualities. And yet 20 years later I was (more or less) happy to see them go—I had to be happy to see them go. We are totally devoted to them when they are little and yet the most we can expect in return when they grow up is that they regard us with bemused and tolerant affection.”

Developmental psychologist Alison Gopnik, “The Supreme Infant,” 2010

When children begin to absorb time, money, and emotional energy, satisfaction with the relationship itself may decline (Doss et al., 2009). This is especially likely among employed women who, more than they expected, may also carry the burden of doing more chores at home. Putting effort into creating an equitable relationship can thus pay double dividends: greater satisfaction, which breeds better parent-child relations (Erel & Burman, 1995).

Although love bears children, children eventually leave home. This departure is a significant and sometimes difficult event. But for most people, an empty nest is a happy place (Adelmann et al., 1989; Gorchoff et al., 2008). Many parents experience a “postlaunch honeymoon,” especially if they maintain close relationships with their children (White & Edwards, 1990). As Daniel Gilbert (2006) has said, “The only known symptom of ‘empty nest syndrome’ is increased smiling.”

To explore the connection between parenting and happiness, engage online with Immersive Learning: How Would You Know If Having Children Relates to Being Happier?

WORK For many adults, the answer to “Who are you?” depends a great deal on the answer to “What do you do?” For women and men, choosing a career path is difficult, especially during bad economic times. Even in the best of times, few students in their first two years of college or university can predict

their later careers.

“To understand your parents’ love, bear your own children.”

Chinese proverb

In the end, happiness is about having work that fits your interests and provides you with a sense of competence and accomplishment. It is giving generously of your time and resources (Mogilner & Norton, 2016; Whillans et al., 2016). It is having a close, supportive companion, or family and friends, who notice and cheer your accomplishments (Campos et al., 2015). And for some, it includes having children who love you and whom you love and feel proud of.

Job satisfaction and life satisfaction

Work can provide us with a sense of identity and competence, and opportunities for accomplishment. Perhaps this is why challenging and interesting occupations enhance people's happiness. For more on work, including discovering your own strengths, see [Appendix A: Psychology at Work](#).

Well-Being Across the Life Span

LOQ 5-22 How does our well-being change across the life span?

To live is to grow older. This moment marks the oldest you have ever been and the youngest you will henceforth be. That means we all can look back with satisfaction or regret, and forward with hope or dread. When asked what they would have done differently if they could relive their lives, people's most common answer has been "taken my education more seriously and

worked harder at it” (Kinnier & Metha, 1989; Roesse & Summerville, 2005). Other regrets—“I should have told my father I loved him,” “I regret that I never went to Europe”—have also focused less on mistakes made than on the things one *failed* to do (Gilovich & Medvec, 1995).

From the teens to midlife, people typically experience a strengthening sense of identity, confidence, and self-esteem (Huang, 2010; Robins & Trzesniewski, 2005). In later life, challenges arise: Income shrinks, work opportunities go away, the body deteriorates, recall fades, energy wanes, family members and friends die or move away, and the great enemy, death, looms ever closer. And for those in the terminal decline phase, life satisfaction does decline as death approaches (Gerstorf et al., 2008).

But prior to the very end, the over-65 years are not notably unhappy. The Gallup Organization asked 658,038 people worldwide to rate their lives on a ladder from 0 (“the worst possible life”) to 10 (“the best possible life”). Age—from 15 to over 90 years—gave no clue to life satisfaction (Morrison et al., 2014). Self-esteem remains stable (Wagner et al., 2013). Positive feelings, supported by enhanced emotional control, tend to grow after midlife, and negative feelings subside (Stone et al., 2010; Urry & Gross, 2010). Compared with younger Chinese and American adults, for example, older adults are *more* attentive to positive news (Isaacowitz, 2012; Wang et al., 2015b).

“When you were born, you cried and the world rejoiced. Live your life in a manner so that when you die the world cries and you rejoice.”

Native American proverb

Compared with teens and young adults, older adults do, however, tend to have a smaller social network, with fewer friendships and greater loneliness (Luhmann & Hawkley, 2016; Wagner et al., 2016). Like people of all ages, older adults are happiest when not alone ([FIGURE 5.24](#)). Older adults experience fewer problems in their relationships—less attachment anxiety, stress, and anger (Chopik et al., 2013; Fingerman & Charles, 2010; Stone et al., 2010). With age, we become more stable and more accepting (Carstensen et al., 2011; Shallcross et al., 2013).

FIGURE 5.24 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.24 Humans are social creatures

Both younger and older adults report greater happiness when spending time with others. (Note this correlation could also reflect happier people being more social.) (Gallup survey data reported by Crabtree, 2011.)

“Still married after all these years?

No mystery.

We are each other’s habit,

And each other’s history.”

Judith Viorst, “The Secret of Staying Married,” 2007

The aging brain may help nurture these positive feelings. Brain scans of older adults show that the amygdala, a neural processing center for emotions, responds less actively to negative events (but not to positive events) (Mather et al., 2004). Brain-wave reactions to negative images also diminish with age (Kisley et al., 2007). As we reach the later chapters of our lives, our brain enables a contented culmination (Mather, 2016).

Moreover, at all ages, the bad feelings we associate with negative events fade faster than do the good feelings we associate with positive events (Walker et al., 2003). This leaves most older people with the comforting feeling that life, on balance, has been mostly good. Thanks to biological, psychological, and social-cultural influences, more and more people flourish into later life ([FIGURE 5.25](#)).

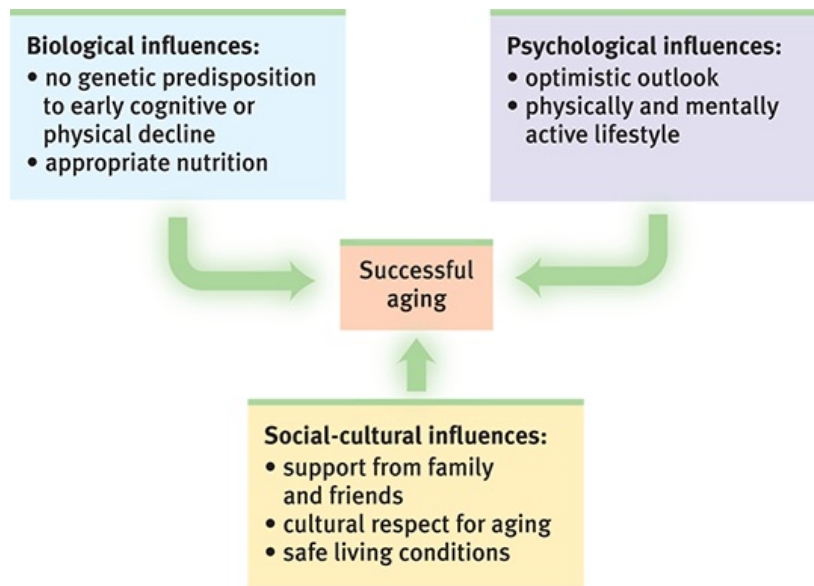

FIGURE 5.25 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 5.25 Biopsychosocial influences on successful aging

“At 70, I would say the advantage is that you take life more calmly. You know that ‘this, too, shall pass’!”

Eleanor Roosevelt, 1954

The resilience of well-being across the life span obscures some interesting age-related emotional differences. When researchers mapped people’s emotional terrain by periodically signaling them with electronic beepers to report their current activities and feelings, they found that teenagers typically come down from elation or up from gloom in less than an hour, but that adult moods are less extreme and more enduring (Csikszentmihalyi & Larson, 1984). As the years go by, feelings mellow (Brose et al., 2015). Highs become less high, lows less low. Compliments provoke less elation and criticisms less despair, as both become merely additional feedback atop a mountain of accumulated praise and blame. As we age, life therefore becomes less of an emotional roller coaster.

RETRIEVAL PRACTICE

RP-15 What are some of the most significant challenges and rewards of growing old?

ANSWER: Challenges: decline of muscular strength, reaction times, stamina, sensory keenness, cardiac output, and immune system functioning. Risk of cognitive decline increases. Rewards: positive feelings tend to grow, negative emotions are less intense, and anger, stress, worry, and social-relationship problems decrease.

Death and Dying

LOQ 5-23 A loved one's death triggers what range of reactions?

Warning: If you begin reading the next paragraph, you will die.

“At 20 we worry about what others think of us. At 40 we don’t care what others think of us. At 60 we discover they haven’t been thinking about us at all.”

Anonymous

But of course, if you hadn’t read this, you would still die in due time. “Time is a great teacher,” noted the nineteenth-century composer Hector Berlioz, “but unfortunately it kills all its pupils.” Death is our inevitable end. We enter the world with a wail, and usually leave it in silence.

“The best thing about being 100 is *no peer pressure*.”

Lewis W. Kuester, 2005, on turning 100

Most of us will also cope with the deaths of relatives and friends. For most people, the most difficult separation they will experience is the death of a partner—a loss suffered by four times more women than men. Maintaining everyday engagements and relationships increases resilience in the face of such a loss (Infurna & Luthar, 2016). But for some, grief is severe, especially when a loved one’s death comes suddenly and before its expected time on the social clock. I [ND] experienced this firsthand when a tragic accident claimed the life of my 60-year-old mother. Such tragedies may trigger a year or more

of memory-laden mourning that eventually subsides to a mild depression (Lehman et al., 1987).

“Love—why, I’ll tell you what love is: It’s you at 75 and her at 71, each of you listening for the other’s step in the next room, each afraid that a sudden silence, a sudden cry, could mean a lifetime’s talk is over.”

Brian Moore, *The Luck of Ginger Coffey*, 1960

For some, the loss is unbearable. One Danish long-term study of more than 1 million people found that about 17,000 of them had suffered the death of a child under 18. In the 5 years following that death, 3 percent of them had a first psychiatric hospitalization, a 67 percent higher rate than among other parents (Li et al., 2005).

Reactions to a loved one’s death range more widely than most suppose. Some cultures encourage public weeping and wailing; others hide grief. Within any culture, individuals differ. Given similar losses, some people grieve hard and long, others less so (Ott et al., 2007). Contrary to popular misconceptions, however:

- Terminally ill and bereaved people do not go through identical predictable stages, such as denial before anger (Friedman & James, 2008; Nolen-Hoeksema & Larson, 1999).
- Those who express the strongest grief immediately do not purge their grief more quickly (Bonanno & Kaltman, 1999; Wortman & Silver, 1989). But grieving parents who try to protect their partner by “staying strong” and not discussing their child’s death may actually prolong the grieving (Stroebe et al., 2013).
- Bereavement therapy and self-help groups offer support, but there is similar healing power in the passing of time, the support of friends, and the act of giving support and help to others (Baddeley & Singer, 2009; Brown et al., 2008; Neimeyer & Currier, 2009). Grieving spouses who talk often with others or receive grief counseling adjust about as well as those who grieve more privately (Bonanno, 2004; Stroebe et al., 2005).

Facing death with dignity and openness helps people complete the life cycle with a sense of life’s meaningfulness and unity—the sense that their

existence has been good and that life and death are parts of an ongoing cycle. Although death may be unwelcome, life itself can be affirmed even at death. This is especially so for people who review their lives not with despair but with what Erik Erikson called a sense of *integrity*—a feeling that one’s life has been meaningful and worthwhile.

“Consider, friend, as you pass by, as you are now, so once was I. As I am now, you too shall be. Prepare, therefore, to follow me.”

Scottish tombstone epitaph

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

By age 65, a person would be most likely to experience a cognitive decline in the ability to

- a. recall and list all the important terms and concepts in a chapter.
- b. select the correct definition in a multiple-choice question.
- c. recall their own birth date.
- d. practice a well-learned skill, such as knitting.

How do cross-sectional and longitudinal studies differ?

Freud defined the healthy adult as one who is able to love and work. Erikson agreed, observing that the adult struggles to attain intimacy and _____.

Contrary to what many people assume,

- a. older people are significantly less happy than adolescents are.
- b. we become less happy as we move from our teen years into midlife.
- c. positive feelings tend to grow after midlife.
- d. those whose children have recently left home—the empty nesters—have the lowest level of happiness of all groups.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Sensory Interaction

ESP—Perception Without Sensation?

“I have perfect vision,” explains acclaimed writer and teacher Heather Sellers. Her vision may be perfect, but her perception is not. In her memoir, *You Don’t Look Like Anyone I Know* (2010), she tells of awkward moments resulting from her lifelong *prosopagnosia*—face blindness.

In college, on a date at the Spaghetti Station, I returned from the bathroom and plunked myself down in the wrong booth, facing the wrong man. I remained unaware he was not my date even as my date (a stranger to me) accosted Wrong Booth Guy, and then stormed out. . . . I do not recognize myself in photos or videos. I can’t recognize my stepsons in the soccer pick-up line; I failed to determine which husband was mine at a party, in the mall, at the market.

“Voice blind” people with *phonagnosia*—an inability to recognize familiar voices—may make similar mistakes. One man flirted on the phone with someone he presumed was his wife, not realizing it was a different woman (Spiegel, 2010).

To avoid being perceived as snobby or aloof, Sellers sometimes fakes recognition. She often smiles at people she passes, in case she knows them. Or she pretends to know the person with whom she is talking. (Similarly, those of us with hearing loss often fake hearing.) But, Sellers points out, there is an upside: When encountering someone who previously irritated her, she typically feels no ill will—she doesn’t recognize the person.

Unlike Sellers, most of us have a functioning area on the underside of our brain’s right hemisphere that helps us recognize a familiar human face as soon as we detect it—in only one-seventh of a second (Jacques & Rossion, 2006; Rossion & Boremanse, 2011). This remarkable ability illustrates a broader principle: *Nature’s sensory gifts enable each animal to obtain*

essential information. Other examples:

- Human ears are most sensitive to sound frequencies that include human voices, especially a baby's cry.
- Frogs, which feed on flying insects, have cells in their eyes that fire only in response to small, dark, moving objects. A frog could starve to death knee-deep in motionless flies. But let one zoom by and the frog's "bug detector" cells snap awake. (As Kermit the Frog said, "Time's fun when you're having flies.")
- Male silkworm moths' odor receptors can detect one-billionth of an ounce of chemical sex attractant per second, released by a female one mile away (Sagan, 1977). That is why there continue to be silkworms.

In this chapter, we'll look at what psychologists have learned about how we sense and perceive our world. We begin by considering some basic principles that apply to all our senses.

Basic Concepts of Sensation and Perception

How do we create meaning from the blizzard of sensory stimuli that bombards our bodies 24 hours a day? Meanwhile, in a silent, cushioned, inner world, our brain floats in utter darkness. By itself, it sees nothing. It hears nothing. It feels nothing. *So, how does the world out there get in?* To phrase the question scientifically: How do we construct our representations of the external world? How do a campfire's flicker, crackle, and smoky scent activate neural connections? And how, from this living neurochemistry, do we create our conscious experience of the fire's motion and temperature, its aroma and beauty? In search of answers, let's examine the basics of sensation and perception.

Processing Sensation and Perception

LOQ LEARNING OBJECTIVE QUESTION 6-1 What are *sensation* and *perception*? What do we mean by *bottom-up processing* and *top-down processing*?

Heather Sellers' curious mix of "perfect vision" and face blindness illustrates the distinction between *sensation* and *perception*. When she looks at a friend, her [sensation](#) is normal. Her [sensory receptors](#) detect the same information yours would, and her nervous system transmits that information to her brain. Her [perception](#)—the processes by which her brain organizes and interprets sensory input—is *almost* normal. Thus, she may recognize people from their hair, gait, voice, or particular physique, just not from their face. Her experience is much like the struggle any human would have trying to recognize a specific penguin.

sensation the process by which our sensory receptors and nervous system receive and represent stimulus energies from our environment.

sensory receptors sensory nerve endings that respond to stimuli.

perception the process of organizing and interpreting sensory information, enabling us to recognize meaningful objects and events.

Under normal circumstances, sensation and perception blend into one continuous process.

- **Bottom-up processing** starts at your sensory receptors and works up to higher levels of processing.
- **Top-down processing** constructs perceptions from this sensory input by drawing on your experience and expectations.

bottom-up processing analysis that begins with the sensory receptors and works up to the brain's integration of sensory information.

top-down processing information processing guided by higher-level mental processes, as when we construct perceptions drawing on our experience and expectations.

As your brain absorbs the information in **FIGURE 6.1**, bottom-up processing enables your sensory systems to detect the lines, angles, and colors that form the flower and leaves. Using top-down processing, you interpret what your senses detect.

FIGURE 6.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
© Sandro Del-Prete/www.sandrodelprete.com

FIGURE 6.1 What's going on here?

Our sensory and perceptual processes work together to help us sort out complex images, including the hidden couple in Sandro Del-Prete's drawing, *The Flowering of Love*.

Transduction

LOQ 6-2 What three steps are basic to all our sensory systems?

Every second of every day, our sensory systems perform an amazing feat:

They convert one form of energy into another. Vision processes light energy. Hearing processes sound waves. All our senses

- *receive* sensory stimulation, often using specialized receptor cells.
- *transform* that stimulation into neural impulses.
- *deliver* the neural information to our brain.

The process of converting one form of energy into another form that our brain can use is called **transduction**. Later in this chapter, we'll focus on individual sensory systems. How do we see? Hear? Feel pain? Taste? Smell? Keep our balance? In each case, one of our sensory systems receives, transforms, and delivers the information to our brain. The field of **psychophysics** studies the relationships between the physical energy we can detect and its effects on our psychological experiences.

transduction conversion of one form of energy into another. In sensation, the transforming of stimulus energies, such as sights, sounds, and smells, into neural impulses our brain can interpret.

psychophysics the study of relationships between the physical characteristics of stimuli, such as their intensity, and our psychological experience of them.

Let's explore some strengths and weaknesses in our ability to detect and interpret stimuli in the vast sea of energy around us.

RETRIEVAL PRACTICE

RP-1 What is the rough distinction between sensation and perception?

ANSWER: *Sensation* is the bottom-up process by which your sensory receptors and nervous system receive and represent stimuli. *Perception* is the top-down process by which your brain creates meaning by organizing and interpreting what your senses detect.

Thresholds

LOQ 6-3 How do absolute thresholds and difference thresholds differ?

At this moment, we are being struck by X-rays and radio waves, ultraviolet and infrared light, and sound waves of very high and very low frequencies. To all of these we are blind and deaf. Other animals with differing needs detect a world that lies beyond our experience. Migrating birds stay on course aided by an internal magnetic compass. Bats and dolphins locate prey using sonar, bouncing echoing sound off objects. Bees navigate on cloudy days by detecting invisible (to us) polarized light.

Our senses open the shades just a crack, allowing us a restricted awareness of this vast sea of energy. But for our needs, this is enough.

Absolute Thresholds

To some kinds of stimuli we are exquisitely sensitive. Standing atop a mountain on an utterly dark, perfectly clear night, most of us could see a candle flame atop another mountain 30 miles away. We could feel the wing of a bee falling on our cheek. We could smell a single drop of perfume in a three-room apartment (Galanter, 1962).

German scientist and philosopher Gustav Fechner (1801–1887) studied the edge of our awareness of these faint stimuli, which he called their **absolute thresholds**—the minimum stimulation necessary to detect a particular light, sound, pressure, taste, or odor 50 percent of the time. To test your absolute threshold for sounds, a hearing specialist would send tones, at varying levels, into each of your ears and record whether you could hear each tone (**FIGURE 6.2**). The test results would show the point where, for any sound frequency, half the time you could detect the sound and half the time you could not. That 50-50 point would define your absolute threshold.

absolute threshold the minimum stimulus energy needed to detect a particular stimulus 50 percent of the time.

FIGURE 6.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Dan Dunkley/Science Source

FIGURE 6.2 Absolute threshold

Can I detect this sound? An *absolute threshold* is the intensity at which a person can detect a stimulus half the time. Hearing tests locate these thresholds for various frequencies.

Detecting a weak stimulus, or signal (such as a hearing-test tone), depends not only on its strength but also on our psychological state—our experience, expectations, motivation, and alertness. **Signal detection theory** predicts when we will detect weak signals (measured as our ratio of “hits” to “false alarms”). Signal detection theorists seek to understand why people respond differently to the same stimuli, and why the same person’s reactions vary as circumstances change.

signal detection theory a theory predicting how and when we detect the presence of a faint stimulus (*signal*) amid background stimulation (*noise*). Assumes there is no single absolute threshold and that detection depends partly on a person’s experience, expectations, motivation, and alertness.

Stimuli you cannot consciously detect 50 percent of the time are **subliminal**—below your absolute threshold (Figure 6.2). One experiment using subliminal stimuli illustrated the deep reality of sexual orientation. As people gazed at the center of a screen, a photo of a nude person was flashed on one side and a scrambled version of the photo on the other side (Jiang et al., 2006). Because the nude images were immediately masked by a colored checkerboard, viewers consciously perceived nothing but flashes of color and so were unable to state on which side the nude had appeared. To test whether

this unseen image unconsciously attracted their attention, the experimenters then flashed a geometric figure to one side or the other. This, too, was quickly followed by a masking stimulus. When asked to give the figure's angle, straight men guessed more accurately when it appeared where a nude woman had been a moment earlier (**FIGURE 6.3**). Gay men (and straight women) guessed more accurately when the geometric figure replaced a nude man. As other experiments confirm, we can evaluate a stimulus even when we are not consciously aware of it—and even when we are unaware of our evaluation (Ferguson & Zayas, 2009). So can we be *controlled* by subliminal messages? For more on that question, see [Thinking Critically About: Subliminal Sensation and Subliminal Persuasion](#).

Thinking Critically About:

Subliminal Sensation and Subliminal Persuasion

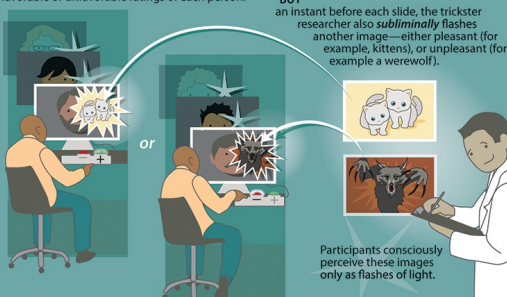

LOO 6-4 How are we affected by subliminal stimuli?

We can be affected by *subliminal* sensations—stimuli so weak that we don't consciously notice them. Researchers use **priming** to activate unconscious associations.

Participant views slides of people and offers either favorable or unfavorable ratings of each person.

BUT an instant before each slide, the trickster researcher also **subliminally** flashes another image—either pleasant (for example, kittens), or unpleasant (for example a werewolf).

Participants consciously perceive these images only as flashes of light.

Will participants' ratings of the faces be affected?

More favorable ratings of people

Yes!

More unfavorable ratings of people

Our two-track mind: Priming happens even though the viewer's brain does not have time to consciously perceive the flashed images. We may evaluate a stimulus even when we are not consciously aware of it.²

So, we can be *primed*, but can we be *persuaded* by subliminal stimuli, for example to lose weight, stop smoking, or improve our memories?

Audio and video messages subliminally (without recipients' conscious awareness) announce:

"I am thin,"
 "Cigarette smoke tastes bad,"
 and
 "I do well on tests. I have total recall of information."

Results from 16 experiments³ showed no powerful, enduring influence on behavior. Not one of the recordings helped more than a placebo, which works only because we believe it will.

1. Krosnick et al., 1992. 2. Ferguson & Zayas, 2009. 3. Greenwald et al., 1991, 1992.
 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

subliminal below one's absolute threshold for conscious awareness.

priming the activation, often unconsciously, of certain associations, thus predisposing one's perception, memory, or response.

FIGURE 6.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Y. Jiang et al., "A Gender- and Sexual Orientation-Dependent Spatial Attention Effect of Invisible Images," *PNAS*, 103, 17048- 17052 © 2006 by The National Academy of Sciences, USA

FIGURE 6.3 The hidden mind

After an image of a nude man or woman was flashed to one side or another, then masked before being perceived, people's attention was unconsciously drawn to images in a way that reflected their sexual orientation (Jiang et al., 2006).

Difference Thresholds

To function effectively, we need absolute thresholds low enough to allow us to detect important sights, sounds, textures, tastes, and smells. We also need to detect small differences among stimuli. A musician must detect minute discrepancies when tuning an instrument. Parents must detect the sound of their own child's voice amid other children's voices. Even after I [DM] had spent two years in Scotland, all lambs' *baas* sounded alike to my ears. But not to their mother's, as I observed. After shearing, each ewe would streak directly to the *baa* of *her* lamb amid the chorus of other distressed lambs.

Eric Isselee/Shutterstock

The **difference threshold** (or the *just noticeable difference [jnd]*) is the minimum difference a person can detect between any two stimuli half the time. That detectable difference increases with the size of the stimulus. If we listen to our music at 40 decibels, we might detect an added 5 decibels. But if we increase the volume to 110 decibels, we probably won't then detect an additional 5-decibel change.

difference threshold the minimum difference between two stimuli required for detection 50 percent of the time. We experience the difference threshold as a *just noticeable difference* (or *jnd*).

In the late 1800s, Ernst Weber described this with a principle so simple and so widely applicable that we still refer to it as **Weber's law**: For an average person to perceive a difference, two stimuli must differ by a constant minimum *percentage* (not a constant *amount*). The exact percentage varies, depending on the stimulus. Two lights, for example, must differ in intensity by 8 percent. Two objects must differ in weight by 2 percent. And two tones must differ in frequency by only 0.3 percent (Teghtsoonian, 1971).

Weber's law the principle that, to be perceived as different, two stimuli must differ by a constant minimum percentage (rather than a constant amount).

The LORD is my shepherd;
I shall not want.
He maketh me to lie down
in green pastures:
he leadeth me
beside the still waters.
He restoreth my soul:
he leadeth me
in the paths of righteousness
for his name's sake.
Yea, though I walk through the valley
of the shadow of death,
I will fear no evil:
for thou art with me;
thy rod and thy staff
they comfort me.
Thou preparest a table before me
in the presence of mine enemies:
thou anointest my head with oil,
my cup runneth over.
Surely goodness and mercy
shall follow me
all the days of my life:
and I will dwell
in the house of the LORD
for ever.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

The difference threshold

In this computer-generated copy of the Twenty-third Psalm, each line of the typeface increases slightly. How many lines are required for you to experience a just noticeable difference?

RETRIEVAL PRACTICE

RP-2 Using sound as your example, explain how these concepts differ: *absolute threshold*, *subliminal stimulation*, and *difference threshold*.

ANSWER: *Absolute threshold* is the minimum stimulation needed to detect a particular sound (such as an approaching bike on the sidewalk behind you) 50 percent of the time. *Subliminal stimulation* happens when, without your awareness, your sensory system processes a sound that is below your absolute threshold. A *difference threshold* is the minimum difference needed to distinguish between two stimuli (such as between the sound of a bike and the sound of a runner coming up behind you).

Sensory Adaptation

LOQ 6-5 What is the function of sensory adaptation?

Sitting down on the bus, you are overwhelmed by your seatmate's heavy perfume. You wonder how she endures it, but within minutes you no longer notice. **Sensory adaptation** has come to your rescue. When constantly exposed to an unchanging stimulus, we become less aware of it because our nerve cells fire less frequently. (To experience sensory adaptation, roll up your sleeve. You will feel it—but only for a few moments.)

sensory adaptation diminished sensitivity as a consequence of constant stimulation.

Why, then, if we stare at an object without flinching, does it *not* vanish from sight? Because, unnoticed by us, our eyes are always moving. This continual flitting from one spot to another ensures that stimulation on the eyes' receptors continually changes (**FIGURE 6.4**).

FIGURE 6.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
© John M. Henderson

FIGURE 6.4 The jumpy eye

Our gaze jumps from one spot to another every third of a second or so, as eye-tracking equipment illustrated as a person looked at this photograph of Edinburgh's Princes Street Gardens (Henderson, 2007). The circles represent visual fixations, and the numbers indicate the time of fixation in milliseconds (300 milliseconds = 3/10ths of a second).

“We need above all to know about changes; no one wants or needs to be reminded 16 hours a day that his shoes are on.”

Neuroscientist David Hubel (1979)

FIGURE 6.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.5 Sensory adaptation: Now you see it, now you don't!

(a) A projector mounted on a contact lens makes the projected image move with the eye. (b) Initially, the person sees the stabilized image—but soon, thanks to sensory adaptation, her eye becomes accustomed to the unchanging stimulus. Rather than the full image, she begins to see fragments fading and reappearing. (From “Stabilized images on the retina,” by R. M. Pritchard. Copyright © 1961 Scientific American, Inc. All Rights Reserved.)

What if we actually could stop our eyes from moving? Would sights seem to vanish, as odors do? To find out, psychologists have devised ingenious instruments that maintain a constant image on the eye's inner surface. Imagine that we have fitted a volunteer, Mary, with such an instrument—a miniature projector mounted on a contact lens ([FIGURE 6.5a](#)). When Mary's eye moves, the image from the projector moves as well. So everywhere that Mary looks, the scene is sure to go.

If we project images through this instrument, what does Mary see? At first, she sees the complete image. But within a few seconds, as her sensory

system begins to fatigue, things get weird. Bit by bit, the image vanishes, only to reappear and then disappear—often in fragments ([Figure 6.5b](#)).

Although sensory adaptation reduces our sensitivity, it offers an important benefit: freedom to focus on informative changes in our environment. The attention-grabbing power of changing stimulation helps explain why our phone's notifications are so hard to ignore. New tweets, likes, snapchats, and breaking news stories pop up and capture our attention. If we're performing other tasks, these intrusions can harm our performance (Stothart et al., 2015). Ditto for TV, which led one researcher to marvel at how TV cuts, zooms, and pans distract, even during interesting conversations: "I cannot for the life of me stop from periodically glancing over to the screen" (Tannenbaum, 2002).

Sensory adaptation even influences how we perceive emotions. By creating a 50-50 morphed blend of an angry face and a scared face, researchers showed that our visual system adapts to a static facial expression by becoming less responsive to it (Butler et al., 2008; [FIGURE 6.6](#)). The effect is created by our brain, not our retinas. We know this because the illusion also works when we view either side image with one eye, and the center image with the other eye.

FIGURE 6.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Scientific American Mind, Andrea Butler, Ipek Oruc, Christopher J. Fox, Jason J.S. Barton.
Brain Research, 29 January 2008.

FIGURE 6.6 Emotion adaptation

Gaze at the angry face on the left for 20 to 30 seconds, then look at the center face (looks scared, yes?). Then gaze at the scared face on the right for 20 to 30 seconds, before returning to the center face (now looks angry, yes?). (From Butler et al., 2008.)

The point to remember: Our sensory receptors are alert to novelty; bore them with repetition and they free our attention for more important things.

We will see this principle again and again: *We perceive the world not exactly as it is, but as it is useful for us to perceive it.*

RETRIEVAL PRACTICE

RP-3 Why is it that after wearing shoes for a while, you cease to notice them (until questions like this draw your attention back to them)?

ANSWER: The shoes provide constant stimulation. Thanks to *sensory adaptation*, we tend to focus primarily on changing stimuli.

Perceptual Set

LOQ 6-6 How do our expectations, contexts, motivation, and emotions influence our perceptions?

To see is to believe. As we less fully appreciate, to believe is to see. Through experience, we come to expect certain results. Those expectations may give us a **perceptual set**, a set of mental tendencies and assumptions that affects, top-down, what we hear, taste, feel, and see.

perceptual set a mental predisposition to perceive one thing and not another.

Consider: Is the center image in **FIGURE 6.7** an old or young woman? What we see in such a drawing can be influenced by first looking at either of the two unambiguous versions (Boring, 1930).

The New Yorker Collection, 2002, Leo Cullum from cartoonbank.com

FIGURE 6.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
W.E. Hill, 1915

FIGURE 6.7 Perceptual set

Show a friend either the left or right image. Then show the center image and ask, “What do you see?” Whether your friend reports seeing an old woman’s face or young woman’s profile may depend on which of the other two drawings was viewed first. In each of those images, the meaning is clear, and it will establish perceptual expectations.

Likewise, in the figure below: Reading from left to right, our expectations cause us to perceive the middle script differently than when reading from top to bottom.

Everyday examples abound of perceptual set—of “mind over mind.” In 1972, a British newspaper published unretouched photographs of a “monster” in Scotland’s Loch Ness—“the most amazing pictures ever taken,” stated the paper. If this information creates in you the same expectations it did in most

of the paper's readers, you, too, will see the monster in a similar photo in **FIGURE 6.8**. But when a skeptical researcher approached the original photos with different expectations, he saw a curved tree limb—as had others the day that photo was shot (Campbell, 1986). With this different perceptual set, you may now notice that the object is floating motionless, with ripples outward in all directions—hardly what we would expect of a swimming monster.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Keystone/Hulton Archive/Getty Images

FIGURE 6.8 Believing is seeing

What do you perceive? Is this Nessie, the Loch Ness monster, or a log?

To believe is also to hear. Consider the kindly airline pilot who, on a

takeoff run, looked over at his sad co-pilot and said, “Cheer up.” Expecting to hear the usual “Gear up,” the co-pilot promptly raised the wheels—before they left the ground (Reason & Mycielska, 1982). Tell people about a couple that has suffered from their experience with some bad sects and (depending on what’s on their minds) they will likely hear something quite different (bad sex). The context of spoken words will determine whether you hear “the stuffy nose” or “the stuff he knows.” And depending on your perceptual set, the weather-forecasting “meteorologist” may become a muscular kidney specialist—your “meaty urologist.”

There Are Two Errors in The The Title Of This Book

Book by Robert M. Martin, 2011

Did you perceive what you expected in this title—and miss the errors? If you are still puzzled, see the explanation below.^{[1](#)}

Or consider this odd question: If you said one thing but heard yourself saying another, what would you think you said? To find out, a clever Swedish research team invited people to name a font color, such as saying “gray” when the word *green* was presented in a gray font (Lind et al., 2014). While the participants heard themselves speaking over a noise-cancelling headset, the wily experimenters occasionally substituted the participant’s own previously recorded voice, such as saying “green” instead of “gray.” Surprisingly, people usually missed the switch—and experienced the inserted word as self-produced. What they heard controlled their perception of what they had just said.

“We hear and apprehend only what we already half know.”

Henry David Thoreau, *Journal*, 1860

Our expectations can also influence our taste perceptions. In one experiment, preschool children, by a 6-to-1 margin, thought french fries tasted better when served in a McDonald’s bag rather than a plain white bag

(Robinson et al., 2007). Another experiment invited campus bar patrons at the Massachusetts Institute of Technology to sample free beer (Lee et al., 2006). When researchers added a few drops of vinegar to a brand-name beer and called it “MIT brew,” the tasters preferred it—unless they had been told they were drinking vinegar-laced beer. In that case, they expected, and usually experienced, a worse taste.

What determines our perceptual set? Through experience we form concepts, or *schemas*, that organize and interpret unfamiliar information. Our preexisting schemas for monsters and tree trunks influence how we apply top-down processing to interpret ambiguous sensations.

In everyday life, stereotypes about gender (another instance of perceptual set) can color perception. Without the obvious cues of pink or blue, people will struggle over whether to call the new baby “he” or “she.” But told an infant is “David,” people (especially children) have perceived “him” as bigger and stronger than when the same infant was called “Diana” (Stern & Karraker, 1989). Some differences, it seems, exist merely in the eyes of their beholders.

Context, Motivation, and Emotion

Perceptual set influences how we interpret stimuli. But our immediate context, and the motivation and emotion we bring to a situation, also affect our interpretations.

CONTEXT Social psychologist Lee Ross invited us to recall our own perceptions in different contexts: “Ever notice that when you’re driving you hate pedestrians, the way they saunter through the crosswalk, almost daring you to hit them, but when you’re walking you hate drivers?” (Jaffe, 2004).

Some other examples of the power of context:

- When holding a gun, people become more likely to perceive another person as also gun-toting—a phenomenon that has led to the shooting of some unarmed people who were actually holding their phone or wallet (Witt & Brockmole, 2012).
- Imagine hearing a noise interrupted by the words “eel is on the wagon.” Likely, you would actually perceive the first word as *wheel*. Given “eel is

on the orange,” you would more likely hear *peel*. In each case, the context creates an expectation that, top-down, influences our perception of a previously heard phrase (Grossberg, 1995).

- Cultural context helps inform our perceptions, so it’s not surprising that people from different cultures view things differently, as in [FIGURE 6.9](#).

FIGURE 6.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.9 Culture and context effects

What is above the woman's head? In one classic study, most rural East Africans questioned said the woman was balancing a metal box or can on her head (a typical way to carry water at that time). They also perceived the family as sitting under a tree. Westerners, used to running water and box-like houses with corners, were more likely to perceive the family as being indoors, with the woman sitting under a window (Gregory & Gombrich, 1973).

- And how is the woman in [FIGURE 6.10](#) feeling? The context provided in [FIGURE 6.11](#) will leave no doubt.

RETRIEVAL PRACTICE

RP-4 Does *perceptual set* involve bottom-up or top-down processing? Why?

ANSWER: It involves top-down processing, because it draws on your experiences, assumptions, and expectations when interpreting stimuli.

MOTIVATION Motives give us energy as we work toward a goal. Like context, they can bias our interpretations of neutral stimuli. Consider these findings:

- Desirable objects, such as a water bottle viewed by a thirsty person, seem closer than they really are (Balcetis & Dunning, 2010). This perceptual bias energizes our going for it.
- A to-be-climbed hill can seem steeper when we are carrying a heavy backpack, and a walking destination further away when we are feeling tired (Burrow et al., 2016; Philbeck & Witt, 2015; Proffitt 2006a,b). Going on a diet can lighten our biological “backpack” (Taylor-Covill & Eves, 2016). When heavy people lose weight, hills and stairs no longer seem so steep.
- A softball appears bigger when you’re hitting well, as researchers observed after asking players to choose a circle the size of the ball they had just hit well or poorly. There’s also a reciprocal phenomenon: Seeing a target as bigger—as happens when athletes focus directly on a target—improves performance (Witt et al., 2012).

“When you’re hitting the ball, it comes at you looking like a grapefruit. When you’re not, it looks like a black-eyed pea.”

Former Major League Baseball player George Scott

EMOTION Other clever experiments have demonstrated that emotions can shove our perceptions in one direction or another.

- Hearing sad music can predispose people to perceive a sad meaning in spoken homophonic words—*mourning* rather than *morning*, *die* rather than *dye*, *pain* rather than *pane* (Halberstadt et al., 1995).
- A hill seems less steep to people who feel others understand them (Oishi et al., 2013b).
- When angry, people more often perceive neutral objects as guns (Baumann & DeSteno, 2010). When made to feel mildly upset by subliminal exposure to a scowling face, people perceive a neutral face as less attractive and likeable (Anderson, E., et al., 2012).

Emotions and motives color our *social* perceptions, too. People more often perceive solitary confinement, sleep deprivation, and cold temperatures as “torture” when experiencing a small dose of such themselves (Nordgren et al., 2011). Spouses who feel loved and appreciated perceive less threat in stressful marital events—“He’s just having a bad day” (Murray et al., 2003).

The moral of all these examples? *Much of what we perceive comes not just from what’s “out there,” but also from what’s behind our eyes and between our ears.* Through top-down processing, our experiences, assumptions, expectations—and even our context, motivation, and emotions—can shape and color our views of reality.

REVIEW Basic Concepts of Sensation and Perception

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only

help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Sensation is to _____ as perception is to _____.

- a. absolute threshold; difference threshold
- b. bottom-up processing; top-down processing
- c. interpretation; detection
- d. grouping; priming

The process by which we organize and interpret sensory information is called _____.

Subliminal stimuli are

- a. too weak to be processed by the brain.
- b. consciously perceived more than 50 percent of the time.
- c. strong enough to affect our behavior at least 75 percent of the time.
- d. below our absolute threshold for conscious awareness.

Another term for *difference threshold* is the _____.

Weber's law states that for a difference to be perceived, two stimuli must differ by

- a. a fixed or constant energy amount.
- b. a constant minimum percentage.
- c. a constantly changing amount.
- d. more than 7 percent.

Sensory adaptation helps us focus on

- a. visual stimuli.
- b. auditory stimuli.
- c. constant features of the environment.
- d. important changes in the environment.

Our perceptual set influences what we perceive. This mental tendency reflects our

- a. experiences, assumptions, and expectations.
- b. sensory adaptation.
- c. priming ability.
- d. difference thresholds.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Vision: Sensory and Perceptual Processing

Light Energy and Eye Structures

LOQ 6-7 What are the characteristics of the energy that we see as visible light? What structures in the eye help focus that energy?

Our eyes receive light energy and *transduce* (transform) it into neural messages. From this neural input, our brain—in one of life’s greatest wonders—then creates what we consciously see. How does such a taken-for-granted yet extraordinary thing happen?

The Stimulus Input: Light Energy

When you look at a bright red tulip, the stimuli striking your eyes are not particles of the color red, but pulses of electromagnetic energy that your visual system *perceives* as red. What we see as visible light is but a thin slice of the wide spectrum of electromagnetic energy shown in [FIGURE 6.12](#). On the spectrum’s one end are the short gamma waves, no longer than the diameter of an atom. On the other end are the mile-long waves of radio transmission. In between is the narrow band visible to us. Other portions are visible to other animals. Bees, for instance, cannot see what we perceive as red but can see ultraviolet light.

FIGURE 6.12 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.12 The wavelengths we see

What we see as light is only a tiny slice of a wide spectrum of electromagnetic energy, which ranges from gamma rays as short as the diameter of an atom to radio waves over a mile long. The wavelengths visible to the human eye (shown enlarged) extend from the shorter waves of blue-violet light to the longer waves of red light.

Light travels in waves, and the shape of those waves influences what we see. Light's **wavelength** is the distance from one wave peak to the next (FIGURE 6.13a). Wavelength determines **hue**, the color we experience, such as the tulip's red petals or green leaves. A light wave's *amplitude*, or height, determines its **intensity**—the amount of energy the wave contains. Intensity influences brightness (Figure 6.13b).

wavelength the distance from the peak of one light or sound wave to the peak of the next. Electromagnetic wavelengths vary from the short blips of gamma

rays to the long pulses of radio transmission.

hue the dimension of color that is determined by the wavelength of light; what we know as the color names *blue*, *green*, and so forth.

intensity the amount of energy in a light wave or sound wave, which influences what we perceive as brightness or loudness. Intensity is determined by the wave's amplitude (height).

FIGURE 6.13 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.13 The physical properties of waves

(a) Waves vary in *wavelength* (the distance between successive peaks). *Frequency*, the number of complete wavelengths that can pass a point in a given time, depends on the wavelength. The shorter the wavelength, the higher the frequency. Wavelength determines the perceived *color* of light. (b) Waves also vary in *amplitude* (the height from peak to trough). Wave amplitude influences the perceived *brightness* of colors.

To understand *how* we transform physical energy into color and meaning, we need to know more about vision's window—the eye.

The Eye

Light enters the eye through the *cornea*, which bends light to help provide focus (FIGURE 6.14). The light then passes through the *pupil*, a small adjustable opening. Surrounding the pupil and controlling its size is the *iris*, a colored muscle that dilates or constricts in response to light intensity. Each iris is so distinctive that an iris-scanning machine can confirm your identity.

FIGURE 6.14 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Pascal Goetgheluck/Science Source

FIGURE 6.14 The eye

Light rays reflected from a candle pass through the cornea, pupil, and lens. The curvature and thickness of the lens change to bring nearby or distant objects into focus on the retina. Rays from the top of the candle strike the bottom of the retina, and those from the left side of the candle strike the right side of the retina. The candle's image on the retina thus appears upside down and reversed.

The iris responds to your cognitive and emotional states. Imagine a sunny sky and your iris will constrict, making your pupil smaller; imagine a dark room and it will dilate (Laeng & Sulutvedt, 2014). The iris also constricts when you are about to answer *No* to a question, or when you feel disgust (de Gee et al., 2014; Goldinger & Papesch, 2012). And when you're feeling amorous, your telltale dilated pupils and dark eyes subtly signal your interest.

After passing through your pupil, light hits the transparent *lens* in your eye. The lens then focuses the light rays into an image on your [retina](#), a multilayered tissue on the eyeball's sensitive inner surface. To focus the rays, the lens changes its curvature and thickness in a process called [accommodation](#).

retina the light-sensitive inner surface of the eye, containing the receptor rods and cones plus layers of neurons that begin the processing of visual information.

accommodation the process by which the eye's lens changes shape to focus near or far objects on the retina.

For centuries, scientists knew that an image of a candle passing through a small opening will cast an inverted mirror image on a dark wall behind. If the

image passing through the pupil casts this sort of upside-down image on the retina, as in [Figure 6.14](#), how can we see the world right side up? The ever-curious Leonardo da Vinci had an idea: Perhaps the eye's watery fluids bend the light rays, reinverting the image to an upright position as it reaches the retina. Unfortunately for da Vinci, that idea was disproved in 1604, when the astronomer and optics expert Johannes Kepler showed that the retina *does* receive upside-down images of the world (Crombie, 1964). So how could we understand such a world? "I leave it," said the befuddled Kepler, "to natural philosophers."

Today's answer: The retina doesn't "see" a whole image. Rather, its millions of receptor cells convert particles of light energy into neural impulses and forward those to the brain, which reassembles them into what we perceive as an upright-seeming image. And along the way, visual information processing percolates through progressively more abstract levels. The process is rather like taking a house apart and, with countless specialized workers, rebuilding it elsewhere. That all of this happens continuously and effortlessly is better than cool: It is awe-inspiring.

Moreover, it happens with astonishing speed. Consider: As a baseball pitcher's fastball approaches home plate, the light signals work their way from the batter's retina to the visual cortex, which then informs the motor cortex, which then sends out orders to contract the muscles—all within the 4/10ths of a second that the ball is in flight.

Information Processing in the Eye and Brain

LOQ 6-8 How do the rods and cones process information, and what is the path information travels from the eye to the brain?

The Eye-to-Brain Pathway

Imagine that you could follow a single light-energy particle after it entered your eye. First, you would thread your way through the retina's sparse outer layer of cells. Then, reaching the back of your eye, you would encounter the retina's nearly 130 million buried receptor cells, the [rods](#) and [cones](#) ([FIGURE 6.15](#)). There, you would see the light energy trigger chemical changes. That

chemical reaction would spark neural signals in nearby *bipolar cells*. You could then watch the bipolar cells activate neighboring *ganglion cells*, whose axons twine together like the strands of a rope to form the [optic nerve](#). After a momentary stopover at the thalamus, the information would fly on to the final destination, your visual cortex, in the occipital lobe at the back of your brain.

rods retinal receptors that detect black, white, and gray, and are sensitive to movement; necessary for peripheral and twilight vision, when cones don't respond.

cones retinal receptors that are concentrated near the center of the retina and that function in daylight or in well-lit conditions. Cones detect fine detail and give rise to color sensations.

optic nerve the nerve that carries neural impulses from the eye to the brain.

FIGURE 6.15 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.15 The retina's reaction to light

The optic nerve is an information highway from the eye to the brain. This nerve can send nearly 1 million messages at once through its nearly 1 million

ganglion fibers. (The auditory nerve, which enables hearing, carries much less information through its mere 30,000 fibers.) We pay a small price for this high-speed connection, however. Your eye has a **blind spot**, with no receptor cells, where the optic nerve leaves the eye ([FIGURE 6.16](#)). Close one eye and you won't see a black hole, however. Without seeking your approval, your brain fills in the hole.

blind spot the point at which the optic nerve leaves the eye, creating a “blind” spot because no receptor cells are located there.

RETRIEVAL PRACTICE

FIGURE 6.16 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.16 The blind spot

RP-5 There are no receptor cells where the optic nerve leaves the eye. This creates a blind spot in your vision. To demonstrate, close your left eye, look at the spot above, and move your face away until one of the cars disappears. (Which one do you predict it will be?) Repeat with your right eye closed—and note that now the other car disappears. Can you explain why?

ANSWER: Your blind spot is on the nose side of each retina, which means that objects to your right may fall onto the right eye's blind spot. Objects to your left may fall on the left eye's blind spot. The blind spot does not normally impair your vision, because your eyes are moving and because one eye catches what the other misses. Moreover, even with only one eye open, our brain gives us a perception without a hole in it.

Rods and cones differ in where they're found and in what they do ([TABLE](#)

6.1). Cones cluster in and around the **fovea**, the retina's area of central focus ([Figure 6.14](#)). Many cones have their own hotline to the brain: One cone transmits its message to a single bipolar cell, which relays the message to the visual cortex (where a large area receives input from the fovea). These direct connections preserve the cones' precise information, making them better able to detect fine detail. Although cones can detect white, they also enable you to perceive color (Sabesan et al., 2016). But in dim light, they become unresponsive, so you see no colors.

TABLE 6.1

Receptors in the Human Eye: Rod-Shaped Rods and Cone-Shaped Cones

	Cones	Rods
<i>Number</i>	6 million	120 million
<i>Location in retina</i>	Center	Periphery
<i>Sensitivity in dim light</i>	Low	High
<i>Color sensitivity</i>	High	Low
<i>Detail sensitivity</i>	High	Low

fovea the central focal point in the retina, around which the eye's cones cluster.

Omikron/Science Source

Unlike cones, which cluster in the center of your retina, *rods* are located around the retina's outer regions. Rods remain sensitive in dim light, and they enable black-and-white vision. Rods have no hotline to the brain. If cones are soloists, rods perform as a chorus. Several rods pool their faint energy output and funnel it onto a single bipolar cell, which sends the combined message to your brain.

Cones and rods each provide a special sensitivity—cones to detail and color, and rods to faint light and peripheral motion. Stop for a minute and experience this rod-cone difference. Pick a word in this sentence and stare directly at it, focusing its image on the cones in your fovea. Notice that words a few inches off to the side appear blurred? They lack detail because their image is striking your retina's outer regions, where rods predominate. Thus, when driving or biking, rods help you detect a car in your peripheral vision well before you perceive its details. And in [FIGURE 6.17](#), which has 12 black dots, you can see barely two at a time, with your brain filling in the less distinct peripheral input (Kitaoka, 2016, adapting Ninio & Stevens, 2000).

FIGURE 6.17 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Akiyoshi Kitaoka

FIGURE 6.17 How many dots do you see at once?

Look at or near any of the twelve and you can see them, but not in your peripheral vision.

When you enter a darkened theater or turn off the light at night, your pupils dilate to allow more light to reach your retina. Your eyes adapt, but fully adapting typically takes 20 minutes or more. This period of dark adaptation matches the average natural twilight transition between the Sun's setting and darkness. How wonderfully made we are.

At the entry level, the retina's neural layers don't just pass along electrical impulses; they also help to encode and analyze sensory information. (The third neural layer in a frog's eye, for example, contains those "bug detector" cells that fire only in response to moving fly-like stimuli.) In human eyes, any given retinal area relays its information to a corresponding location in your visual cortex, in the occipital lobe at the back of your brain ([FIGURE 6.18](#)).

FIGURE 6.18 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.18 Pathway from the eyes to the visual cortex

Ganglion axons forming the optic nerve run to the thalamus, where they synapse with neurons that run to the visual cortex.

The same sensitivity that enables retinal cells to fire messages can lead them to misfire, as you can demonstrate. Turn your eyes to the left, close them, and then gently rub the right side of your right eyelid with your fingertip. Note the patch of light to the left, moving as your finger moves.

Why do you see light? Why at the left? This happens because your retinal cells are so responsive that even pressure triggers them. But your brain interprets their firing as light. Moreover, it interprets the light as coming from the left—the normal direction of light that activates the right side of the retina.

RETRIEVAL PRACTICE

- RP-6 Some nocturnal animals, such as toads, mice, rats, and bats, have impressive night vision thanks to having many more _____ (rods/cones) than _____ (rods/cones) in their retinas. These creatures probably have very poor _____ (color/black-and-white) vision.

ANSWER: rods; cones; color.

RP-7 Cats are able to open their _____ much wider than we can, which allows more light into their eyes so they can see better at night.

ANSWER: pupils

Kruglov_Orda/
Shutterstock

Color Processing

LOQ 6-9 How do we perceive color in the world around us?

We talk as though objects possess color: “A tomato is red.” Recall the old question, “If a tree falls in the forest and no one hears it, does it make a sound?” We can ask the same of color: If no one sees the tomato, is it red?

“Only mind has sight and hearing; all things else are deaf and blind.”

Epicharmus, *Fragments*, 550 b.c.e.

The answer is *No*. First, the tomato is everything *but* red, because it *rejects* (reflects) the long wavelengths of red. Second, the tomato’s color is our mental construction. As Sir Isaac Newton (1704) noted, “The [light] rays are not colored.” Like all aspects of vision, our perception of color resides not in the object itself but in the theater of our brain, as illustrated by our dreaming in color.

One of vision’s most basic and intriguing mysteries is how we see the world in color. How, from the light energy striking the retina, does our brain construct our experience of such a multitude of colors?

Modern detective work on the mystery of color vision began in the

nineteenth century, when Hermann von Helmholtz built on the insights of an English physicist, Thomas Young. They knew that any color can be created by combining the light waves of three primary colors—red, green, and blue. So Young and von Helmholtz formed a hypothesis: The eye must therefore have three corresponding types of color receptors.

Years later, researchers confirmed the [Young-Helmholtz trichromatic \(three-color\) theory](#). By measuring the response of various cones to different color stimuli, they confirmed that the retina does indeed have three types of color receptors, each especially sensitive to the wavelengths of red, green, or blue. When light stimulates combinations of these cones, we see other colors. For example, the retina has no separate receptors especially sensitive to yellow. But when red and green wavelengths stimulate both red-sensitive and green-sensitive cones, we see yellow.

Young-Helmholtz trichromatic (three-color) theory the theory that the retina contains three different types of color receptors—one most sensitive to red, one to green, one to blue—which, when stimulated in combination, can produce the perception of any color.

By one estimate, we can see differences among more than 1 million color variations (Neitz et al., 2001). At least most of us can. About 1 person in 50 is “colorblind.” That person is usually male, because the defect is genetically sex linked. Most people with *color-deficient vision* are not actually blind to all colors. They simply lack functioning red- or green-sensitive cones, or sometimes both. Their vision—perhaps unknown to them, because their lifelong vision *seems* normal—is monochromatic (one-color) or dichromatic (two-color) instead of trichromatic, making it impossible to distinguish the red and green in [FIGURE 6.19](#) (Boynton, 1979). Dogs, too, lack receptors for the wavelengths of red, giving them only limited, dichromatic color vision (Neitz et al., 1989).

FIGURE 6.19 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
BEN SOLOMON/The New York Times/R

FIGURE 6.19 Color-deficient vision

The photo on the left shows how people with red-green deficiency perceived a 2015 Buffalo Bills versus New York Jets football game. “For the 8 percent of Americans like me that are red-green colorblind, this game is a nightmare to watch,” tweeted one fan. “Everyone looks like they’re on the same team,” said another. The photo on the right shows how the game looked for those with normal color vision.

But why do people blind to red and green often still see yellow? And why does yellow appear to be a pure color and not a mixture of red and green, the way purple is of red and blue? As physiologist Ewald Hering—a contemporary of von Helmholtz—noted, trichromatic theory leaves some parts of the color vision mystery unsolved.

Hering found a clue in *afterimages*. Stare at a green square for a while and then look at a white sheet of paper, and you will see red, green’s *opponent color*. Stare at a yellow square and its opponent color, blue, will appear on the white paper. (To experience this, try the flag demonstration in [FIGURE 6.20](#).) Hering formed another hypothesis: Color vision must involve two *additional* color processes, one responsible for red-versus-green perception, and one for blue-versus-yellow perception.

FIGURE 6.20 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.20 Afterimage effect

Stare at the center of the flag for a minute and then shift your eyes to the dot in the white space beside it. What do you see? (After tiring your

neural response to black, green, and yellow, you should see their opponent colors.) Stare at a white wall and note how the size of the flag grows with the projection distance.

Indeed, a century later, researchers also confirmed Hering's hypothesis, now called the [opponent-process theory](#). This concept is tricky, but here is the gist. The researchers found that color vision depends on three sets of opposing retinal processes—*red-green*, *yellow-blue*, and *white-black*. As impulses travel to the visual cortex, some neurons in both the retina and the thalamus are turned “on” by red but turned “off” by green. Others are turned on by green but off by red (DeValois & DeValois, 1975). Like red and green marbles sent down a narrow tube, “red” and “green” messages cannot both travel at once. Red and green are thus opponents, so we see either red or green, not a reddish-green mixture. But red and blue travel in separate channels, so we *can* see a reddish-blue magenta.

opponent-process theory the theory that opposing retinal processes (red-green, yellow-blue, white-black) enable color vision. For example, some cells are stimulated by green and inhibited by red; others are stimulated by red and inhibited by green.

So how does opponent-process theory help us understand afterimages, as in the flag demonstration? Here's the answer (for the green changing to red): First, you stared at green bars, which tired your green response. Then you stared at a white area. White contains all colors, including red. Because you had tired your green response, only the red part of the green-red pairing fired normally.

The present solution to the mystery of color vision is therefore roughly this: *Color processing occurs in two stages.*

The retina's red, green, and blue cones respond in varying degrees to different color stimuli, as the Young-Helmholtz trichromatic theory suggested.

The cones' responses are then processed by opponent-process cells, as Hering's opponent-process theory proposed.

RETRIEVAL PRACTICE

RP-8 What are two key theories of color vision? Are they contradictory or complementary? Explain.

ANSWER: The *Young-Helmholtz trichromatic theory* shows that the retina contains color receptors for red, green, and blue. The *opponent-process theory* shows that we have opponent-process cells in the retina and thalamus for red-green, yellow-blue, and white-black. These theories are complementary and outline the two stages of color vision: (1) The retina's receptors for red, green, and blue respond to different color stimuli. (2) The receptors' signals are then processed by the opponent-process cells on their way to the visual cortex in the brain.

For animated demonstrations and explanations of these cues, engage online with **Concept Practice: Depth Cues**.

Feature Detection

LOQ 6-10 Where are feature detectors located, and what do they do?

Scientists once likened the brain to a movie screen on which the eye projected images. Then along came David Hubel and Torsten Wiesel (1979), who showed that our visual processing deconstructs visual images and then reassembles them. Hubel and Wiesel received a Nobel Prize for their work on **feature detectors**, nerve cells in the occipital lobe's visual cortex that respond to a scene's specific features—to particular edges, lines, angles, and movements.

feature detectors nerve cells in the brain that respond to specific features of the stimulus, such as shape, angle, or movement.

Using microelectrodes, they had discovered that some neurons fired actively when cats were shown lines at one angle, while other neurons responded to lines at a different angle. They surmised that these specialized neurons, now known as feature detectors, receive information from individual ganglion cells in the retina. Feature detectors pass this specific information to other cortical areas, where teams of cells (*supercell clusters*) respond to more complex patterns.

For biologically important objects and events, monkey brains (and surely ours as well) have a “vast visual encyclopedia” distributed as specialized cells (Perrett et al., 1990, 1992, 1994). These cells respond to one type of stimulus, such as a specific gaze, head angle, posture, or body movement. Other supercell clusters integrate this information and fire only when the cues collectively indicate the direction of someone’s attention and approach. This instant analysis, which aided our ancestors’ survival, also helps a soccer player anticipate where to strike the ball, and a driver anticipate a pedestrian’s next movement.

One temporal lobe area by your right ear ([FIGURE 6.21](#)) enables you to perceive faces and, thanks to a specialized neural network, to recognize them from varied viewpoints (Connor, 2010). If stimulated in this *fusiform face area*, you might spontaneously see faces—as did the participant who reported to an experimenter that “You just turned into someone else. Your face metamorphosed” (Koch, 2015). If this face recognition region were damaged, you might recognize other forms and objects, but not familiar faces.

Alex Livesey/FIFA/Getty Images

Well-developed supercells

In this 2011 World Cup match, USA's Abby Wambach instantly processed visual information about the positions and movements of Brazil's defenders and goalkeeper and somehow managed to get the ball around them all and into the net.

When researchers temporarily disrupt the brain's face-processing areas with magnetic pulses, people are unable to recognize faces. But they can still recognize other objects, such as houses, because the brain's face perception occurs separately from its object perception (McKone et al., 2007; Pitcher et al., 2007). Thus, functional MRI (fMRI) scans have shown different brain areas activating when people viewed varied objects (Downing et al., 2001). Brain activity is so specific that, with the help of brain scans, researchers can tell whether people are “looking at a shoe, a chair, or a face, based on the pattern of their brain activity,” (Haxby, 2001).

Parallel Processing

LOQ 6-11 How does the brain use parallel processing to construct visual perceptions?

Our brain achieves these and other remarkable feats by **parallel processing**: doing many things at once. To analyze a visual scene, the brain divides it into subdimensions—motion, form, depth, color—and works on each aspect simultaneously (**FIGURE 6.22**). We then construct our perceptions by integrating (*binding*) the separate but parallel work of these different visual teams (Livingstone & Hubel, 1988).

parallel processing processing many aspects of a problem simultaneously; the brain's natural mode of information processing for many functions, including vision.

FIGURE 6.22 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.22 Parallel processing

Studies of patients with brain damage suggest that the brain delegates

the work of processing motion, form, depth, and color to different areas. After taking a scene apart, the brain integrates these subdimensions into the perceived image. How does the brain do this? The answer to this *binding problem* (how does the brain bind multiple sensory inputs into a single perception?) is the Holy Grail of vision research.

To recognize a face, your brain integrates information projected by your retinas to several visual cortex areas and compares it with stored information, thus enabling your fusiform face area to recognize the face: *Grandmother!* Scientists have debated whether this stored information is contained in a single cell or, more likely, distributed over a vast network of cells. Some supercells—*grandmother cells*—do appear to respond very selectively to 1 or 2 faces in 100 (Bowers, 2009; Quiroga et al., 2013). The whole face recognition process requires tremendous brain power: 30 percent of the cortex (10 times the brain area devoted to hearing).

Destroy or disable the neural workstation for a visual subtask, and something peculiar results, as happened to “Mrs. M.” (Hoffman, 1998). After a stroke damaged areas near the rear of both sides of her brain, she could not perceive motion. People in a room seemed “suddenly here or there but I [had] not seen them moving.” Pouring tea into a cup was a challenge because the fluid appeared frozen—she could not perceive it rising in the cup.

For a 4-minute depiction of a blindsight patient, see the **Video—Blindsight: Seeing Without Awareness**.

After stroke or surgery has damaged the brain’s visual cortex, others have experienced *blindsight*. Shown a series of sticks, they report seeing nothing. Yet when asked to guess whether the sticks are vertical or horizontal, their visual intuition typically offers the correct response. When told, “You got them all right,” they are astounded. There is, it seems, a second “mind”—a parallel processing system—operating unseen. These separate visual systems for perceiving and for acting illustrate once again the astonishing dual processing of our two-track mind.

* * *

Think about the wonders of visual processing. As you read these words, the letters reflect light rays onto your retina, which triggers a process that sends

formless nerve impulses to several areas of your brain, which integrate the information and decode its meaning. The amazing result: We have transferred information across time and space, from our minds to your mind ([FIGURE 6.23](#)). That all of this happens instantly, effortlessly, and continuously is indeed awesome. As Roger Sperry (1985) observed, the “insights of science give added, not lessened, reasons for awe, respect, and reverence.”

“I am fearfully and wonderfully made.”

King David, Psalm 139:14

RETRIEVAL PRACTICE

RP-9 What is the rapid sequence of events that occurs when you see and recognize a friend?

ANSWER: Light waves reflect off the person and travel into your eyes. Receptor cells in your retina convert the light waves' energy into millions of neural impulses sent to your brain. Your brain's detector cells and work teams process the subdimensions of this visual input—including color, movement, form, and depth—separately but simultaneously. Your brain interprets this information, based on previously stored information and your expectations, and forms a conscious perception of your friend.

Perceptual Organization

LOQ**6-12**

How did the Gestalt psychologists understand perceptual organization, and how do figure-ground and grouping principles contribute to our perceptions?

It's one thing to understand how we see colors and shapes. But how do we organize and interpret those sights (or sounds, or tastes, or smells) so that they become *meaningful* perceptions—a rose in bloom, a familiar face, a sunset?

Early in the twentieth century, a group of German psychologists noticed that people who are given a cluster of sensations tend to organize them into a **gestalt**, a German word meaning a “form” or a “whole.” As we look straight ahead, we cannot separate the perceived scene into our left and right fields of view (each as seen with one eye closed). Our conscious perception is, at every moment, a seamless scene—an integrated whole.

gestalt an organized whole. Gestalt psychologists emphasized our tendency to integrate pieces of information into meaningful wholes.

Consider **FIGURE 6.24**: The individual elements of this figure, called a *Necker cube*, are really nothing but eight blue circles, each containing three converging white lines. When we view these elements all together, however, we see a cube that sometimes reverses direction. This phenomenon nicely illustrates a favorite saying of Gestalt psychologists: *In perception, the whole may exceed the sum of its parts.*

FIGURE 6.24 A Necker cube

What do you see: circles with white lines, or a cube? If you stare at the cube, you may notice that it reverses location, moving the tiny X in the center from the front edge to the back. At times, the cube may seem to float forward, with circles behind it. At other times, the circles may become holes through which the cube appears, as though it were floating behind them. There is far more to perception than meets the eye. (From Bradley et al., 1976.)

Over the years, the Gestalt psychologists demonstrated many principles we use to organize our sensations into perceptions (Wagemans et al., 2012a,b). Underlying all of them is a fundamental truth: *Our brain does more than register information about the world.* Perception is not just opening a shutter and letting a picture print itself on the brain. We filter incoming information and *construct* perceptions. Mind matters.

Form Perception

Imagine designing a video-computer system that, like your eye-brain system, could recognize faces at a glance. What abilities would it need?

FIGURE AND GROUND To start with, the system would need to perceive **figure-ground**—to separate faces from their backgrounds. In our eye-brain system, this is our first perceptual task—perceiving any object (the *figure*) as distinct from its surroundings (the *ground*). As you read, the words are the figure; the white space is the ground. This perception applies to our hearing, too. As you hear voices at a party, the one you attend to becomes the figure; all others are part of the ground. Sometimes the same stimulus can trigger more than one perception. In **FIGURE 6.25**, the figure-ground relationship continually reverses. First we see the vase, then the faces, but we always organize the stimulus into a figure seen against a ground.

figure-ground the organization of the visual field into objects (the *figures*) that stand out from their surroundings (the *ground*).

FIGURE 6.25 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 6.25 Reversible figure and ground

GROUPING Having discriminated figure from ground, we (and our video-computer system) must also organize the figure into a *meaningful* form. Some basic features of a scene—such as color, movement, and light-dark contrast—we process instantly and automatically (Treisman, 1987). Our mind brings order and form to other stimuli by following certain rules for **grouping**, also identified by the Gestalt psychologists. These rules, which we apply even as infants and even in our touch perceptions, illustrate how the perceived whole differs from the sum of its parts, rather as water differs from

its hydrogen and oxygen parts (Gallace & Spence, 2011; Quinn et al., 2002; Rock & Palmer, 1990). Three examples:

Proximity We group nearby figures together. We see not six separate lines, but three sets of two lines.

Continuity We perceive smooth, continuous patterns rather than discontinuous ones. This pattern could be a series of alternating semicircles, but we perceive it as two continuous lines—one wavy, one straight.

Closure We fill in gaps to create a complete, whole object. Thus we assume that the circles on the left are complete but partially blocked by the (illusory) triangle. Add nothing more than little line segments to close off the circles and your brain stops constructing a triangle.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Such principles usually help us construct reality. Sometimes, however, they lead us astray, as when we look at the doghouse in [FIGURE 6.26](#).

FIGURE 6.26 Grouping principles

What's the secret to this impossible doghouse? You probably perceive this doghouse as a gestalt—a whole (though impossible) structure. Actually, your brain imposes this sense of wholeness on the picture. As [Figure 6.30](#) shows, Gestalt grouping principles such as closure and continuity are at work here.

grouping the perceptual tendency to organize stimuli into coherent groups.

RETRIEVAL PRACTICE

RP-10 In terms of perception, a band's lead singer would be considered _____ (figure/ground), and the other musicians would be considered _____ (figure/ground).

ANSWER: figure; ground.

RP-11 What do we mean when we say that, in perception, “the whole may exceed the sum of its parts”?

ANSWER: Gestalt psychologists used this saying to describe our

perceptual tendency to organize clusters of sensations into meaningful forms or coherent groups.

Depth Perception

LOQ 6-13 How do we use binocular and monocular cues to see in three dimensions, and how do we perceive motion?

Our eye-brain system performs many remarkable feats, among which is [depth perception](#). From the two-dimensional images falling on our retinas, we somehow organize three-dimensional perceptions that let us estimate the distance of an oncoming car or the height of a faraway house. How do we acquire this ability? Are we born with it? Did we learn it?

depth perception the ability to see objects in three dimensions although the images that strike the retina are two-dimensional; allows us to judge distance.

As Eleanor Gibson picnicked on the rim of the Grand Canyon, her scientific curiosity kicked in. She wondered: *Would a toddler peering over the rim perceive the dangerous drop-off and draw back?* To answer that question and others, Gibson and Richard Walk (1960) designed a series of experiments in their Cornell University laboratory using a [visual cliff](#)—a model of a cliff with a “drop-off” area that was actually covered by sturdy glass. They placed 6- to 14-month-old infants on the edge of the “cliff” and had the infants’ mothers coax them to crawl out onto the glass ([FIGURE 6.27](#)). Most infants refused to do so, indicating that they could perceive depth.

visual cliff a laboratory device for testing depth perception in infants and young animals.

FIGURE 6.27 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.27 Visual cliff

Eleanor Gibson and Richard Walk devised this miniature cliff with a glass-covered drop-off to determine whether crawling infants and newborn animals can perceive depth. Even when coaxed, infants are reluctant to venture onto the glass over the cliff.

See the **Video: Experiments** for a helpful tutorial animation about this type of research method.

Had they *learned* to perceive depth? Learning is surely part of the answer because crawling, no matter when it begins, seems to increase an infant's fear of heights (Adolph et al., 2014; Campos et al., 1992). But depth perception is also partly innate. Mobile newborn animals—even those with no visual experience (including young kittens, a day-old goat, and newly hatched chicks)—also refuse to venture across the visual cliff. Thus, biology prepares us to be wary of heights, and experience amplifies that fear.

"I can't go on living with such lousy depth perception!"

Tom Cheney/New Yorker Cartoon/Cartoon Bank

If we were to build the ability to perceive depth into our video-computer system, what rules might enable it to convert two-dimensional images into a single three-dimensional perception? A good place to start would be the depth cues our brain receives from information supplied by one or both of our eyes.

BINOCULAR CUES People who see with two eyes perceive depth thanks partly to **binocular cues**. Here's an example: With both eyes open, hold two pens or pencils in front of you and touch their tips together. Now do so with one eye closed. A more difficult task, yes?

binocular cue a depth cue, such as retinal disparity, that depends on the use of two eyes.

We use binocular cues to judge the distance of nearby objects. One such cue is **retinal disparity**. Because your eyes are about 2 inches apart, your retinas receive slightly different images of the world. By comparing these two images, your brain can judge how close an object is to you. The greater the disparity (difference) between the two retinal images, the closer the object. Try it. Hold your two index fingers, with the tips about half an inch apart, directly in front of your nose, and your retinas will receive quite different views. If you close one eye and then the other, you can see the difference. (Bring your fingers close and you can create a finger sausage, as in **FIGURE 6.28**.) At a greater distance—say, when you hold your fingers at arm's length—the disparity is smaller.

retinal disparity a binocular cue for perceiving depth. By comparing retinal images from the two eyes, the brain computes distance—the greater the disparity (difference) between the two images, the closer the object.

FIGURE 6.28 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.28 The floating finger sausage

Hold your two index fingers about 5 inches in front of your eyes, with their tips half an inch apart. Now look beyond them and note the weird result. Move your fingers out farther and the retinal disparity—and the finger sausage—will shrink.

We could easily include retinal disparity in our video-computer system.

Moviemakers sometimes film a scene with two cameras placed a few inches apart. Viewers then watch the film through glasses that allow the left eye to see only the image from the left camera, and the right eye to see only the image from the right camera. The resulting effect, as 3-D movie fans know, mimics or exaggerates normal retinal disparity, giving the perception of depth.

MONOCULAR CUES How do we judge whether a person is 10 or 100 meters away? Retinal disparity won't help us here, because there won't be much difference between the images cast on our right and left retinas. At such distances, we depend on **monocular cues** (depth cues available to each eye separately). See **FIGURE 6.29** for some examples.

monocular cue a depth cue, such as interposition or linear perspective, available to either eye alone.

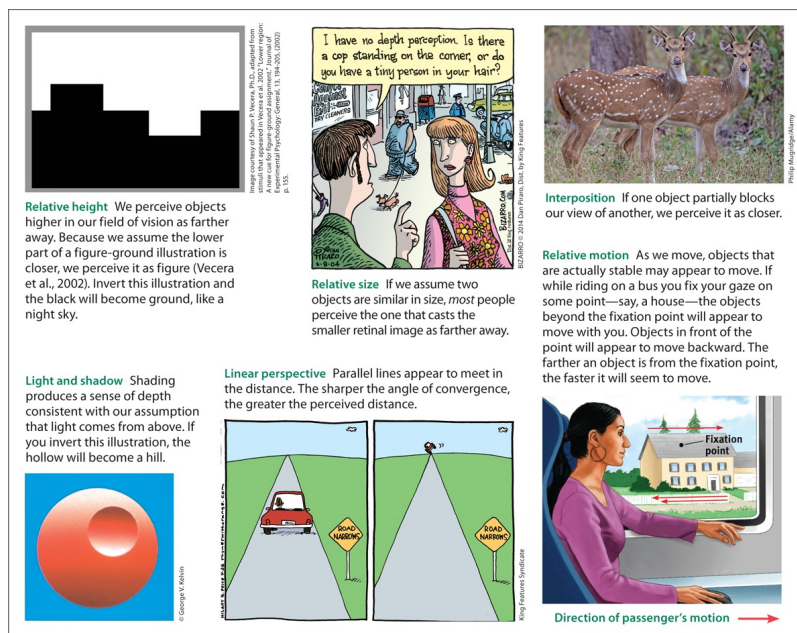

FIGURE 6.29 Monocular depth cues

Carnivorous animals, including humans, have eyes that enable forward focus on prey and offer binocular vision-enhanced depth perception. Grazing herbivores, such as horses and sheep, typically have eyes on the

sides of their skull. Although lacking binocular depth perception, they have sweeping peripheral vision.

RETRIEVAL PRACTICE

RP-12 How do we normally perceive depth?

ANSWER: We are normally able to perceive depth thanks to (1) binocular cues (such as retinal disparity), and (2) monocular cues (which include relative height, relative size, interposition, linear perspective, light and shadow, and relative motion).

Motion Perception

Imagine that, like Mrs. M. described earlier, you could perceive the world as having color, form, and depth but that you could not see motion. Not only would you be unable to bike or drive, you would have trouble writing, eating, and walking.

Normally your brain computes motion based partly on its assumption that shrinking objects are retreating (not getting smaller) and enlarging objects are approaching. But you are imperfect at motion perception. In young children, this ability to correctly perceive approaching (and enlarging) vehicles is not yet fully developed, which puts them at risk for pedestrian accidents (Wann et al., 2011). But it's not just children who have occasional difficulties with motion perception. Our adult brain is sometimes tricked into believing what it is not seeing. When large and small objects move at the same speed, the large objects appear to move more slowly. Thus, trains seem to move slower than cars, and jumbo jets seem to land more slowly than little jets.

FIGURE 6.30 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.30 The solution

Another view of the impossible doghouse in [Figure 6.26](#) reveals the secrets of this illusion. From the photo angle in [Figure 6.26](#), the grouping principle of closure leads us to perceive the boards as continuous.

Our brain also perceives a rapid series of slightly varying images as continuous movement (a phenomenon called *stroboscopic movement*). As film animators know well, a superfast slide show of 24 still pictures a second will create an illusion of movement. We construct that motion in our heads, just as we construct movement in blinking marquees and holiday lights. We perceive two adjacent stationary lights blinking on and off in quick succession as one single light moving back and forth. Lighted signs exploit this [phi phenomenon](#) with a succession of lights that creates the impression of, say, a moving arrow.

phi phenomenon an illusion of movement created when two or more adjacent

lights blink on and off in quick succession.

Perceptual Constancy

LOQ 6-14 How do perceptual constancies help us construct meaningful perceptions?

So far, we have noted that our video-computer system must perceive objects as we do—as having a distinct form, location, and perhaps motion. Its next task is to recognize objects without being deceived by changes in their color, brightness, shape, or size—a *top-down* process called **perceptual constancy**. Regardless of the viewing angle, distance, and illumination, we can identify people and things in less time than it takes to draw a breath. This feat, which challenges even advanced computers, would be a monumental challenge for a video-computer system.

perceptual constancy perceiving objects as unchanging (having consistent color, brightness, shape, and size) even as illumination and retinal images change.

COLOR AND BRIGHTNESS CONSTANCIES Our experience of color depends on an object's *context*. This would be clear if you viewed an isolated tomato through a paper tube over the course of a day. As the light—and thus the tomato's reflected wavelengths—changed, the tomato's color would also seem to change. But if you discarded the paper tube and viewed the tomato as one item in a salad bowl, its perceived color would remain essentially constant. This perception of consistent color we call *color constancy*.

“From there to here, from here to there, funny things are everywhere.”

Dr. Seuss, *One Fish, Two Fish, Red Fish, Blue Fish*, 1960

Though we take color constancy for granted, this ability is truly remarkable. A blue poker chip under indoor lighting reflects wavelengths that

match those reflected by a sunlit gold chip (Jameson, 1985). Yet bring a goldfinch indoors and it won't look like a bluebird. The color is not in the bird's feathers. We see color thanks to our brain's computations of the light reflected by an object *relative to the objects surrounding it*. [FIGURE 6.31](#) dramatically illustrates the ability of a blue object to appear very different in three different contexts. Yet we have no trouble seeing these disks as blue. Nor does knowing the truth—that these disks are identically colored—diminish our perception that they are quite different. Because we construct our perceptions, we can simultaneously accept alternative objective and subjective realities.

FIGURE 6.31 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
R. Beau Lotto/Lottolab

FIGURE 6.31 Color depends on context

(a) Believe it or not, these three blue disks are identical in color. (b) Remove the surrounding context and see what results.

Brightness constancy (also called *lightness constancy*) similarly depends on context. We perceive an object as having a constant brightness even as its illumination varies. This perception of constancy depends on *relative luminance*—the amount of light an object reflects *relative to its surroundings* ([FIGURE 6.32](#)). White paper reflects 90 percent of the light falling on it; black paper, only 10 percent. Although a black paper viewed in sunlight may reflect 100 times more light than does a white paper viewed indoors, it will still look black (McBurney & Collings, 1984). But if you view sunlit black paper through a narrow tube so nothing else is visible, it may look gray,

because in bright sunshine it reflects a fair amount of light. View it without the tube and it is again black, because it reflects much less light than the objects around it.

FIGURE 6.32 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.32 Relative luminance

Because of its surrounding context, we perceive Square A as lighter than Square B. But believe it or not, they are identical. To channel comedian Richard Pryor, “Who you gonna believe: me, or your lying eyes?” If you believe your lying eyes—actually, your lying brain—you can photocopy (or screen-capture and print) the illustration, then cut out the squares and compare them. (Information from Edward Adelson.)

This principle—that we perceive objects not in isolation but in their environmental context—matters to artists, interior decorators, and clothing designers. Our perception of the color and brightness of a wall or of a streak of paint on a canvas is determined not just by the paint in the can but by the surrounding colors. The take-home lesson: *Comparisons govern our perceptions.*

SHAPE AND SIZE CONSTANCIES Thanks to *shape constancy*, we perceive the form of familiar objects, such as the door in [FIGURE 6.33](#), as constant even while our retinas receive changing images of them. Our brain manages this feat because visual cortex neurons rapidly learn to associate different views of an object (Li & DiCarlo, 2008).

FIGURE 6.33 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 6.33 Shape constancy

A door casts an increasingly trapezoidal image on our retinas as it opens. Yet we still perceive it as rectangular.

Thanks to *size constancy*, we perceive an object as having a constant size, even while our distance from it varies. We assume a car is large enough to carry people, even when we see its tiny image from two blocks away. This assumption also illustrates the close connection between perceived *distance* and perceived *size*. Perceiving an object's distance gives us cues to its size. Likewise, knowing its general size—that the object is a car—provides us with cues to its distance.

“Sometimes I wonder: Why is that Frisbee getting bigger? And then it hits me.”

Anonymous

Even in size-distance judgments, however, we consider an object's context. This interplay between perceived size and perceived distance helps explain several well-known illusions, including the *Moon illusion*: The Moon looks up to 50 percent larger when near the horizon than when high in the sky. Can you imagine why?

For at least 22 centuries, scholars have wondered (Hershenson, 1989). One reason is that monocular cues to an object's distance make the horizon Moon

seem farther away. If it's farther away, our brain assumes, it must be larger than the Moon high in the night sky (Kaufman & Kaufman, 2000). But again, if you use a paper tube to take away the distance cue, the horizon Moon will immediately seem smaller.

Perceptual illusions reinforce a fundamental lesson: Perception is not merely a projection of the world onto our brain. Rather, our sensations are disassembled into information bits that our brain then reassembles into its own functional model of the external world. During this reassembly process, our assumptions—such as the usual relationship between distance and size—can lead us astray. *Our brain constructs our perceptions.*

To experience more visual illusions, and to understand what they reveal about how you perceive the world, visit **PsychSim 6: Visual Illusions**.

* * *

Form perception, depth perception, motion perception, and perceptual constancies illuminate how we organize our visual experiences. Perceptual organization applies to our other senses, too. Listening to an unfamiliar language, we have trouble hearing where one word stops and the next one begins. Listening to our own language, we automatically hear distinct words. This, too, reflects perceptual organization. But it is more, for we even organize a string of letters—THEDOGATEMEAT—into words that make an intelligible phrase, more likely “The dog ate meat” than “The do gate me at” (McBurney & Collings, 1984). This process involves not only the organization we’ve been discussing, but also interpretation—discerning meaning in what we perceive.

Perceptual Interpretation

Philosophers have debated whether our perceptual abilities should be credited to our nature or our nurture. To what extent do we *learn* to perceive? German philosopher Immanuel Kant (1724–1804) maintained that knowledge comes from our *inborn* ways of organizing sensory experiences. Indeed, we come equipped to process sensory information. But British philosopher John Locke (1632–1704) argued that through our experiences we also *learn* to perceive

the world. Indeed, we learn to link an object's distance with its size. So, just how important is experience? How radically does it shape our perceptual interpretations?

Experience and Visual Perception

LOQ 6-15 What does research on restored vision, sensory restriction, and perceptual adaptation reveal about the effects of experience on perception?

“Let us then suppose the mind to be, as we say, white paper void of all characters, without any ideas: How comes it to be furnished? . . . To this I answer, in one word, from EXPERIENCE.”

John Locke, *An Essay Concerning Human Understanding*, 1690

RESTORED VISION AND SENSORY RESTRICTION Writing to John Locke, William Molyneux wondered whether “a man *born* blind, and now adult, taught by his *touch* to distinguish between a cube and a sphere” could, if made to see, visually distinguish the two. Locke’s answer was *No*, because the man would never have *learned* to see the difference.

Molyneux’s hypothetical case has since been put to the test with a few dozen adults who, though blind from birth, later gained sight (Gregory, 1978; Huber et al., 2015; von Senden, 1932). Most were born with cataracts—clouded lenses that allowed them to see only diffused light, rather as a sighted person might see a foggy image through a Ping-Pong ball sliced in half. After cataract surgery, the patients could distinguish figure from ground and could differentiate colors—suggesting that these aspects of perception are innate. But much as Locke supposed, they often remained unable to visually recognize objects that were familiar by touch.

Seeking to gain more control than is provided by clinical cases, researchers have restricted the vision of infant kittens (Hubel & Wiesel, 1963). After infancy, when their vision was restored, the kittens behaved much like the humans born with cataracts. They could distinguish color and brightness, but not the form of a circle from that of a square. Their eyes had

not degenerated; their retinas still relayed signals to their visual cortex. But lacking early stimulation, their brain's cortical cells had not developed normal connections. Thus, the animals remained functionally blind to shape.

Marcio Jose Sanchez/AP Images

Learning to see

At age 3, Mike May lost his vision in an explosion. Decades later, after a new cornea restored vision to his right eye, he got his first look at his wife and children. Alas, although signals were now reaching his visual cortex, it lacked the experience to interpret them. May could not recognize expressions, or faces, apart from features such as hair. Yet he can see an object in motion and has learned to navigate his world and to marvel at such things as dust floating in sunlight (Abrams, 2002; Gorlick, 2010; Huber et al., 2015).

Surgery on children in India reveals that those who are blind from birth can benefit from removal of cataracts, and the younger they are, the more they benefit. But their visual acuity (sharpness) may never be normal (Chatterjee, 2015; Gandhi et al., 2014). For normal sensory and perceptual development, there is a *critical period*—an optimal period when exposure to

certain stimuli or experiences is required.

Once this critical period has passed, sensory restrictions later in life do no permanent harm. When researchers cover an adult animal's eye for several months, its vision will be unaffected after the eye patch is removed. When surgeons remove cataracts that developed during late adulthood, most people are thrilled at the return to normal vision.

PERCEPTUAL ADAPTATION Given a new pair of glasses, we may feel slightly disoriented, even dizzy. Within a day or two, we adjust. Our [perceptual adaptation](#) to changed visual input makes the world seem normal again. But imagine a far more dramatic new pair of glasses—one that shifts the apparent location of objects 40 degrees to the left. When you first toss a ball to a friend, it sails off to the left. Walking forward to shake hands with someone, you veer to the left.

perceptual adaptation the ability to adjust to changed sensory input, including an artificially displaced or even inverted visual field.

Could you adapt to this distorted world? Not if you were a baby chicken. When fitted with such lenses, baby chicks continue to peck where food grains *seem* to be (Hess, 1956; Rossi, 1968). But we humans adapt to distorting lenses quickly. Within a few minutes your throws would again be accurate, your stride on target. Remove the lenses and you would experience an aftereffect: At first your throws would err in the *opposite* direction, sailing off to the right; but again, within minutes you would readapt.

Indeed, given an even more radical pair of glasses—one that literally turns the world upside down—you could still adapt. Psychologist George Stratton (1896) experienced this. He invented, and for eight days wore, optical headgear that flipped left to right *and* up to down, making him the first person to experience a right-side-up retinal image while standing upright. The ground was up, the sky was down.

Courtesy of Hubert Dolezal

Perceptual adaptation

“Oops, missed,” thought researcher Hubert Dolezal as he attempted a handshake while viewing the world through inverting goggles. Yet, believe it or not, kittens, monkeys, and humans can adapt to an inverted world.

At first, when Stratton wanted to walk, he found himself searching for his feet, which were now “up.” Eating was nearly impossible. He became nauseated and depressed. But he persisted, and by the eighth day he could comfortably reach for an object and, if his hands were in view, could walk without bumping into things. When Stratton finally removed the headgear, he readapted quickly. So did research participants who wore such gear in later experiments—while riding a motorcycle, skiing the Alps, or flying an airplane (Dolezal, 1982; Kohler, 1962). By actively moving about in their topsy-turvy world, they adapted to their new context and learned to coordinate their movements.

So do we learn to perceive the world? In part we do, as we constantly adjust to changed sensory input. Research on critical periods teaches us that early nurture sculpts what nature has provided. In less dramatic ways, nurture

continues to do so throughout our lives. Experience guides, sustains, and maintains the brain pathways that enable our perceptions.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The characteristic of light that determines the color we experience, such as blue or green, is _____.

The amplitude of a light wave determines our perception of

- a. brightness.
- b. color.
- c. meaning.
- d. distance.

The blind spot in your retina is located where

- a. there are rods but no cones.
- b. there are cones but no rods.
- c. the optic nerve leaves the eye.
- d. the bipolar cells meet the ganglion cells.

Cones are the eye's receptor cells that are especially sensitive to _____ light and are responsible for our _____ vision.

- a. bright; black-and-white
- b. dim; color
- c. bright; color
- d. dim; black-and-white

Two theories together account for color vision. The Young-Helmholtz trichromatic theory shows that the eye contains _____, and Hering's theory accounts for the nervous system's having _____.

- a. opposing retinal processes; three pairs of color receptors
- b. opponent-process cells; three types of color receptors
- c. three pairs of color receptors; opposing retinal processes
- d. three types of color receptors; opponent-process cells

What mental processes allow you to perceive a lemon as yellow?

The cells in the visual cortex that respond to certain lines, edges, and angles are called _____.

The brain's ability to process many aspects of an object or a problem simultaneously is called _____.

Our tendencies to fill in the gaps and to perceive a pattern as continuous are two different examples of the organizing principle called

- a. interposition.
- b. depth perception.
- c. shape constancy.
- d. grouping.

In listening to a concert, you attend to the solo instrument and perceive the orchestra as accompaniment. This illustrates the organizing principle of

- a. figure-ground.
- b. shape constancy.
- c. grouping.
- d. depth perception.

The visual cliff experiments suggest that

- a. infants have not yet developed depth perception.
- b. crawling human infants and very young animals perceive depth.
- c. we have no way of knowing whether infants can perceive depth.
- d. unlike other species, humans are able to perceive depth in infancy.

Depth perception underlies our ability to

- a. group similar items in a gestalt.
- b. perceive objects as having a constant shape or form.
- c. judge distances.
- d. fill in the gaps in a figure.

Two examples of _____ depth cues are interposition and linear perspective.

Perceiving a tomato as consistently red, despite lighting shifts, is an example of

- a. shape constancy.
- b. perceptual constancy.
- c. a binocular cue.
- d. continuity.

After surgery to restore vision, adults who had been blind from birth had difficulty

- a. recognizing objects by touch.
- b. recognizing objects by sight.
- c. distinguishing figure from ground.
- d. distinguishing between bright and dim light.

In experiments, people have worn glasses that turned their visual fields upside down. After a period of adjustment, they learned to function quite well. This ability is called _____.

The Nonvisual Senses

Hearing

Like our other senses, our hearing, or [audition](#), helps us adapt and survive. Hearing provides information and enables relationships. Hearing humanizes us; people seem more thoughtful, competent, and likable when we hear them than when we merely read their words (Schroeder & Epley, 2015, 2016). And hearing is pretty spectacular. It lets us communicate invisibly, shooting unseen air waves across space and receiving the same from others. Hearing loss is therefore an invisible disability. To not catch someone's name, to not grasp what someone is asking, and to miss the hilarious joke is to be deprived of what others know, and sometimes to feel excluded. As a person with hearing loss, I [DM] know the feeling, and can understand why adults with significant hearing loss experience a doubled risk of depression (Li et al., 2014).

audition the sense or act of hearing.

Most of us, however, can hear a wide range of sounds, and the ones we hear best are those in the range of the human voice. With normal hearing, we are remarkably sensitive to faint sounds, such as a child's whimper. (If our ears were only slightly more sensitive, we would hear a constant hiss from the movement of air molecules.) Our distant ancestors' survival depended on this keen hearing when hunting or being hunted.

Zdorov Kirill Vladimirovich/Shutterstock; sbarabu/Shutterstock

The sounds of music

A violin's short, fast waves create a high pitch. The longer, slower waves of a cello or bass create a lower pitch. Differences in the waves' height, or amplitude, also create differing degrees of loudness.

We are also remarkably attuned to sound variations. Among thousands of possible voices, we easily recognize an unseen friend's. Moreover, hearing is fast. "It might take you a full second to notice something out of the corner of your eye, turn your head toward it, recognize it, and respond to it," notes auditory neuroscientist Seth Horowitz (2012). "The same reaction to a new or sudden sound happens at least 10 times as fast." A fraction of a second after such events stimulate your ear's receptors, millions of neurons have simultaneously coordinated in extracting the essential features, comparing them with past experience, and identifying the stimulus (Freeman, 1991). For hearing as for our other senses, we wonder: How do we do it?

The Stimulus Input: Sound Waves

LOQ 6-16 What are the characteristics of air pressure waves that we hear as sound?

Draw a bow across a violin, and you will unleash the energy of sound waves. Air molecules, each bumping into the next, create waves of compressed and expanded air, like the ripples on a pond circling out from a tossed stone. As we swim in our ocean of moving air molecules, our ears detect these brief air pressure changes.

Like light waves, sound waves vary in shape ([FIGURE 6.34](#)). The height, or *amplitude*, of sound waves determines their perceived *loudness*. Their length, or *frequency*, determines the *pitch* (the high or low tone) we experience. Long waves have low frequency—and low pitch. Short waves have high frequency—and high pitch. Sound waves produced by a soprano are much shorter and faster than those produced by a baritone singer.

FIGURE 6.34 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.34 The physical properties of waves

(a) Waves vary in *wavelength* (the distance between successive peaks). *Frequency*, the number of complete wavelengths that can pass a point in a given time, depends on the wavelength. The shorter the wavelength, the higher the frequency. Wavelength determines the *pitch* of sound. (b) Waves also vary in *amplitude* (the height from peak to trough). Wave amplitude influences sound *intensity*.

frequency the number of complete wavelengths that pass a point in a given time (for example, per second).

pitch a tone's experienced highness or lowness; depends on frequency.

We measure sounds in *decibels*, with zero decibels representing the absolute threshold for hearing. Every 10 decibels correspond to a tenfold increase in sound intensity. Thus, normal conversation (60 decibels) is 10,000

times more intense than a 20-decibel whisper. And a temporarily tolerable 100-decibel passing subway train is 10 billion times more intense than the faintest detectable sound. If prolonged, exposure to sounds above 85 decibels can produce hearing loss. Tell that to football fans of the NFL's Kansas City Chiefs who, in 2014, broke the Guinness World Record for the noisiest stadium at 142 decibels (Liberman, 2015). Hear today, gone tomorrow.

The Ear

LOQ 6-17 How does the ear transform sound energy into neural messages?

How does vibrating air trigger nerve impulses that your brain can decode as sounds? The process begins when sound waves strike your *eardrum*, causing this tight membrane to vibrate ([FIGURE 6.35](#)).

FIGURE 6.35 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.35 Hear here: How we transform sound waves into nerve impulses that our brain interprets

(a) The outer ear funnels sound waves to the eardrum. The bones of the middle ear (hammer, anvil, and stirrup) amplify and relay the eardrum's vibrations through the oval window into the fluid-filled cochlea. (b) As shown in this detail of the middle and inner ear, the resulting pressure changes in the cochlear fluid cause the basilar membrane to ripple, bending the hair cells on its surface. Hair cell movements trigger impulses at the base of the nerve cells, whose fibers converge to form the auditory nerve. That nerve sends neural messages to the thalamus and on to the auditory cortex.

In your [middle ear](#), a piston made of three tiny bones (the *hammer*, *anvil*, and *stirrup*) picks up the vibrations and transmits them to the [cochlea](#), a snail-shaped tube in your [inner ear](#).

middle ear the chamber between the eardrum and cochlea containing three tiny bones (hammer, anvil, and stirrup) that concentrate the vibrations of the eardrum on the cochlea's oval window.

cochlea [KOHK-lee-uh] a coiled, bony, fluid-filled tube in the inner ear; sound waves traveling through the cochlear fluid trigger nerve impulses.

inner ear the innermost part of the ear, containing the cochlea, semicircular canals, and vestibular sacs.

The incoming vibrations then cause the cochlea's membrane-covered opening (the *oval window*) to vibrate, jostling the fluid inside the cochlea. This motion causes ripples in the *basilar membrane*, bending the *hair cells* lining its surface, rather like wheat stalks bending in the wind.

The hair cell movements in turn trigger impulses in adjacent nerve cells, whose axons converge to form the *auditory nerve*. The auditory nerve carries the neural messages to your thalamus and then on to the *auditory cortex* in your brain's temporal lobe.

From vibrating air, to tiny moving bones, to fluid waves, to electrical impulses to the brain: Voilà! You hear!

Perhaps the most intriguing part of the hearing process is the hair cells —“quivering bundles that let us hear” thanks to their “extreme sensitivity and extreme speed” (Goldberg, 2007). A cochlea has 16,000 of them, which sounds like a lot until we compare that with an eye's 130 million or so photoreceptors. But consider a hair cell's responsiveness. Deflect the tiny bundles of *cilia* on its tip by only the width of an atom—imagine!—and the alert hair cell, thanks to a special protein at its tip, will trigger a neural response (Corey et al., 2004).

Damage to the cochlea's hair cell receptors or the auditory nerve can cause [sensorineural hearing loss](#) (or nerve deafness). With auditory nerve damage, people may hear sound but have trouble discerning what someone is saying

(Liberman, 2015).

sensorineural hearing loss hearing loss caused by damage to the cochlea's receptor cells or to the auditory nerves; the most common form of hearing loss, also called *nerve deafness*.

Occasionally, disease damages hair cell receptors, but more often the culprits are biological changes linked with heredity and aging, and prolonged exposure to ear-splitting noise or music. Sensorineural hearing loss is more common than [conduction hearing loss](#), which is caused by damage to the mechanical system that conducts sound waves to the cochlea.

conduction hearing loss a less common form of hearing loss, caused by damage to the mechanical system that conducts sound waves to the cochlea.

The cochlea's hair cells have been likened to carpet fibers. Walk around on them and they will spring back. But leave a heavy piece of furniture on them and they may never rebound. As a general rule, any noise we cannot talk over (loud machinery, fans screaming at a sports event, music blasting at maximum volume) may be harmful, especially if prolonged and repeated (Roesser, 1998) ([FIGURE 6.36](#)). And if our ears ring after such experiences, we have been bad to our unhappy hair cells. As pain alerts us to possible bodily harm, ringing of the ears alerts us to possible hearing damage. It is hearing's equivalent of bleeding.

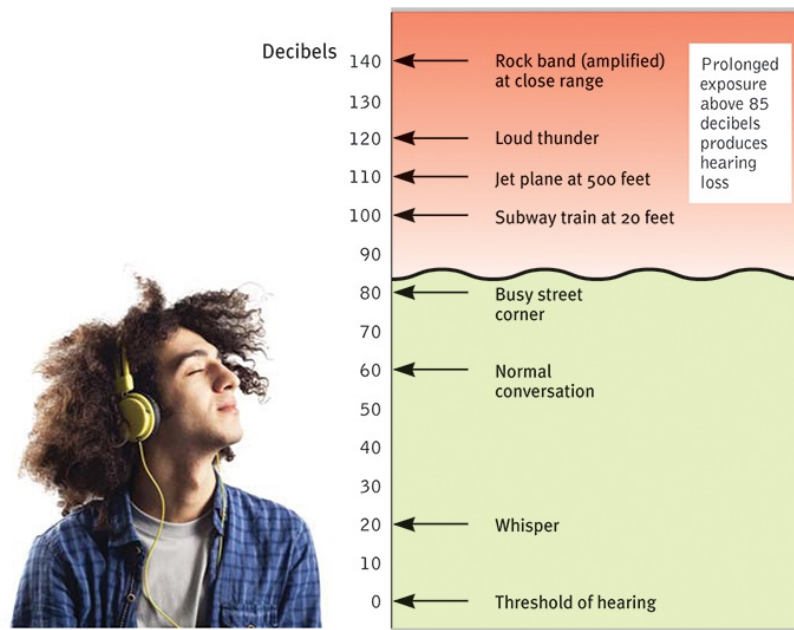

FIGURE 6.36 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
sebra/Shutterstock

FIGURE 6.36 The intensity of some common sounds

One study of 3 million Germans found that professional musicians had almost four times the normal rate of noise-induced hearing loss (Schink et al., 2014). Some modern headphones block out environmental noise, reducing the need to blast the music at dangerous volumes.

Worldwide, 1.23 billion people are challenged by hearing loss (Global Burden of Disease, 2015). Since the early 1990s, teen hearing loss has risen by a third and now affects 1 in 5 teens (Shargorodsky et al., 2010). Exposure to loud music, both live and through headphones, is a culprit: After three hours of a rock concert averaging 99 decibels, 54 percent of teens reported not hearing as well, and 1 in 4 had ringing in their ears. Teen boys more than teen girls or adults blast themselves with loud volumes for long periods (Zogby, 2006). Males' greater noise exposure may help explain why men's hearing tends to be less acute than women's. But male or female, those who spend many hours in a loud nightclub, behind a power mower, or above a jackhammer should wear earplugs, or they risk needing a hearing aid later. "Condoms or, safer yet, abstinence," say sex educators. "Earplugs or walk away," say hearing educators.

Nerve deafness cannot be reversed. For now, the only way to restore hearing is a sort of bionic ear—a [cochlear implant](#). Some 50,000 people, including some 30,000 children, receive these electronic devices each year

(Hochmair, 2013). The implants translate sounds into electrical signals that, wired into the cochlea's nerves, convey information about sound to the brain. When given to deaf kittens and human infants, cochlear implants have seemed to trigger an “awakening” of the pertinent brain area (Klinke et al., 1999; Sireteanu, 1999). These devices can help children become proficient in oral communication (especially if they receive them as preschoolers or ideally before age 1) (Dettman et al., 2007; Schorr et al., 2005). Hearing, like vision, has a *critical period*. Cochlear implants can help restore hearing for most adults, but only if their brain learned to process sound during childhood. The restored hearing can also reduce social isolation and the risk of depression (Mosnier et al., 2015).

cochlear implant a device for converting sounds into electrical signals and stimulating the auditory nerve through electrodes threaded into the cochlea.

RETRIEVAL PRACTICE

RP-13 What are the basic steps in transforming sound waves into perceived sound?

ANSWER: The *outer ear* collects sound waves, which are translated into mechanical waves by the *middle ear* and turned into fluid waves in the *inner ear*. The *auditory nerve* then translates the energy into electrical waves and sends them to the brain, which perceives and interprets the sound.

RP-14 The amplitude of a sound wave determines our perception of _____ (loudness/pitch).

ANSWER: loudness.

RP-15 The longer the sound waves, the _____ (lower/higher) their frequency and the _____ (higher/lower) their pitch.

ANSWER: lower; lower

Perceiving Loudness, Pitch, and Location

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Hardware for hearing

Cochlear implants work by translating sounds into electrical signals that are transmitted to the cochlea and, via the auditory nerve, relayed to the brain.

LOQ 6-18 How do we detect loudness, discriminate pitch, and locate sounds?

RESPONDING TO LOUD AND SOFT SOUNDS How do we detect loudness? If you guessed that it's related to the intensity of a hair cell's response, you'd be wrong. Rather, a soft, pure tone activates only the few hair cells attuned to its frequency. Given louder sounds, neighboring hair cells also respond. Thus, your brain interprets loudness from the *number* of activated hair cells.

If a hair cell loses sensitivity to soft sounds, it may still respond to loud sounds. This helps explain another surprise: Really loud sounds may seem loud to people with or without normal hearing. As a person with hearing loss, I [DM] used to wonder what really loud music must sound like to people with normal hearing. Now I realize it sounds much the same; where we differ is in

our perception of soft sounds. This is why we hard-of-hearing people do not want *all* sounds (loud and soft) amplified. We like sound *compressed*, which means harder-to-hear sounds are amplified more than loud sounds (a feature of today's digital hearing aids).

HEARING DIFFERENT PITCHES How do we know whether a sound is the high-frequency, high-pitched chirp of a bird or the low-frequency, low-pitched roar of a truck? Current thinking on how we discriminate pitch combines two theories.

- **Place theory** presumes that we hear different pitches because different sound waves trigger activity at different places along the cochlea's basilar membrane. Thus, the brain determines a sound's pitch by recognizing the specific place (on the membrane) that is generating the neural signal. When Nobel laureate-to-be Georg von Békésy (1957) cut holes in the cochleas of guinea pigs and human cadavers and looked inside with a microscope, he discovered that the cochlea vibrated, rather like a shaken bedsheet, in response to sound. High frequencies produced large vibrations near the beginning of the cochlea's membrane. Low frequencies vibrated more of the membrane and were not so easily localized. So there is a problem: Place theory can explain how we hear high-pitched sounds but not low-pitched sounds.
- **Frequency theory** (also called *temporal theory*) suggests an alternative: The brain reads pitch by monitoring the frequency of neural impulses traveling up the auditory nerve. The whole basilar membrane vibrates with the incoming sound wave, triggering neural impulses to the brain at the same rate as the sound wave. If the sound wave has a frequency of 100 waves per second, then 100 pulses per second travel up the auditory nerve. But frequency theory also has a problem: An individual neuron cannot fire faster than 1000 times per second. How, then, can we sense sounds with frequencies above 1000 waves per second (roughly the upper third of a piano keyboard)? Enter the *volley principle*: Like soldiers who alternate firing so that some can shoot while others reload, neural cells can alternate firing. By firing in rapid succession, they can achieve a *combined frequency* above 1000 waves per second.

place theory in hearing, the theory that links the pitch we hear with the place where the cochlea's membrane is stimulated.

frequency theory in hearing, the theory that the rate of nerve impulses traveling up the auditory nerve matches the frequency of a tone, thus enabling us to sense its pitch. (Also called *temporal theory*.)

So, place theory and frequency theory work together to enable our perception of pitch. Place theory best explains how we sense *high pitches*. Frequency theory, extended by the volley principle, also explains how we sense *low pitches*. Finally, some combination of place and frequency theories likely explains how we sense *pitches in the intermediate range*.

RETRIEVAL PRACTICE

RP-16 Which theory of pitch perception would best explain a symphony audience's enjoyment of a high-pitched piccolo? How about a low-pitched cello?

ANSWER: place theory; frequency theory

LOCATING SOUNDS Why don't we have one big ear—perhaps above our one nose? “All the better to hear you with,” as the wolf said to Little Red Riding Hood. Thanks to the placement of our two ears, we enjoy stereophonic (“three-dimensional”) hearing. Two ears are better than one for at least two reasons ([FIGURE 6.37](#)). If a car to your right honks, your right ear will receive a more *intense* sound, and it will receive the sound slightly *sooner* than your left ear.

FIGURE 6.37 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.37 How we locate sounds

Sound waves strike one ear sooner and more intensely than the other. From this information, our nimble brain can compute the sound's location. As you might therefore expect, people who lose all hearing in one ear often have difficulty locating sounds.

Because sound travels 761 miles per hour and human ears are but 6 inches apart, the intensity difference and the time lag are extremely small. A just noticeable difference in the direction of two sound sources corresponds to a time difference of just 0.000027 second! Lucky for us, our supersensitive auditory system can detect such minute differences (Brown & Deffenbacher, 1979; Middlebrooks & Green, 1991).

For an interactive review of how we perceive sound, visit **PsychSim 6: The Auditory System**. For an animated explanation, visit **Concept Practice: The Auditory Pathway**.

The Other Senses

Sharks and dogs rely on their outstanding sense of smell, aided by large smell-related brain areas. Our human brain allocates more real estate to seeing and hearing. But extraordinary happenings also occur within our other senses. Without our senses of touch, taste, smell, and body position and movement, we humans would be seriously handicapped, and our capacities for enjoying the world would be greatly diminished.

Touch

LOQ 6-19 How do we sense touch?

Touch is vital. Right from the start, touch aids our development. Infant rats deprived of their mother's grooming produce less growth hormone and have a lower metabolic rate—a good way to keep alive until the mother returns, but a reaction that stunts growth if prolonged. Infant monkeys that were allowed to see, hear, and smell—but not touch—their mother became desperately unhappy (Suomi et al., 1976). Premature human babies gain weight faster and go home sooner if they are stimulated by hand massage (Field et al., 2006). As adults, we still yearn to touch—to kiss, to stroke, to snuggle.

© Jose Luis Pelaez, Inc./Blend Images/Corbis

The precious sense of touch

As William James wrote in his *Principles of Psychology* (1890), “Touch is both the alpha and omega of affection.”

Humorist Dave Barry was perhaps right to jest that your skin “keeps people from seeing the inside of your body, which is repulsive, and it

prevents your organs from falling onto the ground.” But skin does much more. Touching various spots on the skin with a soft hair, a warm or cool wire, and the point of a pin reveals that some spots are especially sensitive to *pressure*, others to *warmth*, others to *cold*, still others to *pain*. Our “sense of touch” is actually a mix of these four basic and distinct skin senses, and our other skin sensations are variations of pressure, warmth, cold, and pain. For example, stroking adjacent pressure spots creates a tickle. Repeated gentle stroking of a pain spot creates an itching sensation. Touching adjacent cold and pressure spots triggers a sense of wetness (which you can experience by touching dry, cold metal).

Touch sensations involve more than tactile stimulation, however. A self-administered tickle produces less somatosensory cortex activation than does the same tickle from something or someone else (Blakemore et al., 1998). Likewise, a sensual leg caress evokes a different somatosensory cortex response when a heterosexual man believes it comes from an attractive woman rather than a man (Gazzola et al., 2012). Such responses reveal how quickly cognition influences our brain’s sensory response.

Jeff Riedel/Contour/Getty Images

“Pain is a gift.”

So said a doctor studying Ashlyn Blocker, who has a rare genetic mutation that prevents her from feeling pain. At birth, she didn't cry. As a child, she ran around for two days on a broken ankle. She has put her hands on a hot machine and burned the flesh off. And she has reached into boiling water to retrieve a dropped spoon. “Everyone in my class asks me about it, and I say, ‘I can feel pressure, but I can't feel pain.’ *Pain!* I cannot feel it!”

Pain

LOQ 6-20 What biological, psychological, and social-cultural influences affect our experience of pain? How do placebos, distraction, and hypnosis help control pain?

Be thankful for occasional pain. Pain is your body's way of telling you something has gone wrong. Drawing your attention to a burn, a break, or a sprain, pain orders you to change your behavior—"Stay off that ankle!" Pain also serves psychological purposes. It provides a contrast that amplifies our experiences of pleasure. It enhances our self-awareness. And it arouses others' empathy and promotes social connections (Bastian et al., 2014).

The rare people born without the ability to feel pain may experience severe injury or even death before early adulthood. Without the discomfort that makes us shift position, their joints can fail from excess strain. Without the warnings of pain, infections can run wild and injuries can accumulate (Neese, 1991).

More numerous are those who live with chronic pain, which is rather like an alarm that won't shut off. Persistent backaches, arthritis, headaches, and cancer-related pain prompt two questions: What is pain? How might we control it?

UNDERSTANDING PAIN Our experience of pain reflects both *bottom-up* sensations and *top-down* cognition. Pain is a biopsychosocial event (Hadjistavropoulos et al., 2011). As such, pain experiences vary widely, from group to group and from person to person. Viewing pain from the biological, psychological, and social-cultural perspectives can help us better understand it, and also help us cope with it and treat it ([FIGURE 6.38](#)).

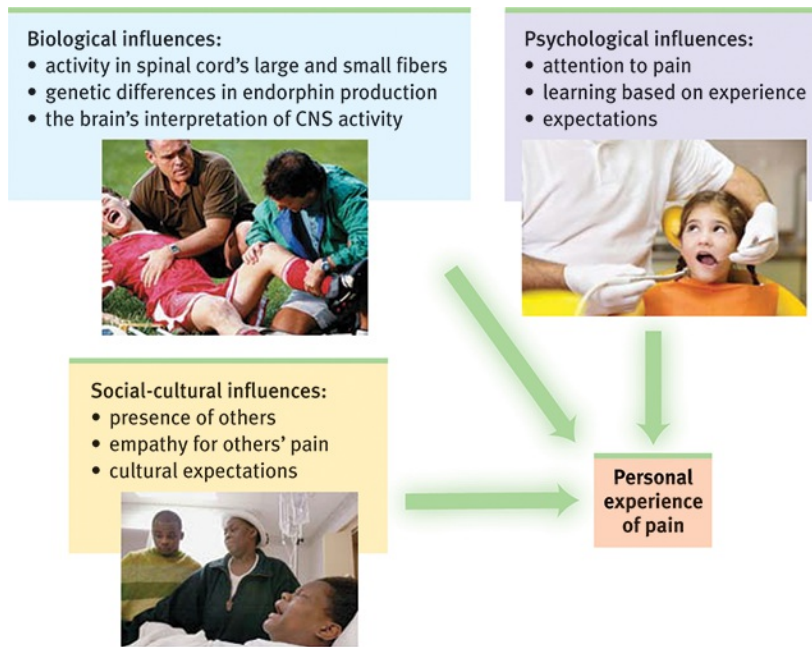

FIGURE 6.38 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Barros & Barros/Getty Images; Robert Nickelsberg/Getty Images; Halfpoint/Shutterstock

FIGURE 6.38 Biopsychosocial approach to pain

Our experience of pain is much more than the neural messages sent to our brain.

Biological Influences Pain is a physical event produced by your senses. But pain differs from some of your other sensations. No one type of stimulus triggers pain the way light triggers vision. And no specialized receptors process pain signals the way your retina receptors react to light rays. Instead, sensory receptors called *nociceptors*—mostly in your skin, but also in your muscles and organs—detect hurtful temperatures, pressure, or chemicals ([FIGURE 6.39](#)).

FIGURE 6.39 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.39 The pain circuit

Sensory receptors (*nociceptors*) respond to potentially damaging stimuli by sending an impulse to the spinal cord, which passes the message to the brain, which interprets the signal as pain.

Your experience of pain depends in part on the genes you inherited and on your physical characteristics (Gatchel et al., 2007; Reimann et al., 2010). Women are more sensitive to pain than men are (their senses of hearing and smell also tend to be more sensitive) (Ruau et al., 2012; Wickelgren, 2009).

No pain theory can explain all available findings. One useful model, [gate-control theory](#), was proposed by psychologist Ronald Melzack and biologist Patrick Wall (1965, 1983; Melzack & Katz, 2013, with support from Foster et al., 2015). The theory suggests that the spinal cord contains a neurological “gate” that controls the transmission of pain messages to the brain.

gate-control theory the theory that the spinal cord contains a neurological “gate” that blocks pain signals or allows them to pass on to the brain. The “gate” is opened by the activity of pain signals traveling up small nerve fibers and is closed by activity in larger fibers or by information coming from the brain.

Small spinal cord nerve fibers conduct most pain signals. Melzack and

Wall theorized that when tissue is injured, the small fibers activate and open the gate. The pain signals can then travel to your brain, and you feel pain. But large-fiber activity (stimulated by massage, electric stimulation, or acupuncture) can close the gate, blocking pain signals. Brain-to-spinal-cord messages can also close the gate. Thus, chronic pain can be treated both by “gate-closing” stimulation, such as massage, and by mental activity, such as distraction (Wall, 2000).

But pain is not merely a physical phenomenon of injured nerves sending impulses to a definable brain or spinal cord area—like pulling on a rope to ring a bell. The brain can also create pain, as it does in *phantom limb sensations* after a limb amputation. Without normal sensory input, the brain may misinterpret and amplify spontaneous but irrelevant central nervous system activity. As the dreamer may see with eyes closed, so 7 in 10 such people feel pain or movement in nonexistent limbs (Melzack, 1992, 2005). Some may even try to lift a cup with a phantom hand, or step off a bed onto a phantom leg. Even those born without a limb sometimes perceive sensations from the absent arm or leg. The brain, Melzack (1998) has surmised, comes prepared to anticipate “that it will be getting information from a body that has limbs.”

Phantoms may haunt other senses too. People with hearing loss often experience the sound of silence: *tinnitus*, the phantom sound of ringing in the ears that’s accompanied by auditory brain activity (Sedley et al., 2015). Those who lose vision to glaucoma, cataracts, diabetes, or macular degeneration may experience phantom sights—nonthreatening hallucinations (Ramachandran & Blakeslee, 1998). Others with nerve damage in the systems for tasting and smelling have experienced phantom tastes or smells, such as ice water that seems sickeningly sweet or fresh air that reeks of rotten food (Goode, 1999). *The point to remember:* We feel, see, hear, taste, and smell with our brain, which can sense even without functioning senses.

Psychological Influences One powerful influence on our perception of pain is the attention we focus on it. Athletes, focused on winning, may perceive pain differently and play through it.

We also seem to edit our *memories* of pain, which often differ from the pain we actually experienced. In experiments, and after painful experiences such as medical procedures or childbirth, people overlook a pain’s duration. Their memory snapshots instead record two factors: their pain’s *peak*

moment (which can lead them to recall variable pain, with peaks, as worse [Chajut et al., 2014; Stone et al., 2005]), and how much pain they felt at the *end*. In one experiment, people immersed one hand in painfully cold water for 60 seconds, and then the other hand in the same painfully cold water for 60 seconds followed by a slightly less painful 30 seconds more (Kahneman et al., 1993). Which experience would you expect they recalled as most painful?

Curiously, when asked which trial they would prefer to repeat, most preferred the 90-second trial, with more net pain—but less pain at the end. Physicians have used this principle with patients undergoing colon exams—lengthening the discomfort by a minute, but lessening its intensity at the end (Kahneman, 1999). Patients experiencing this taper-down treatment later recalled the exam as less painful than did those whose pain ended abruptly. (If, as a painful root canal is ending, the oral surgeon asks if you’d rather go home or have a few more minutes of milder discomfort, there’s a case to be made for prolonging your hurt.)

The end of an experience can color our memory of pleasures, too. In one simple experiment, some people, on receiving a fifth and last piece of chocolate, were told it was their “next” one. Others, told it was their “last” piece, liked it better and also rated the whole experiment as being more enjoyable (O’Brien & Ellsworth, 2012). Endings matter.

Reinhold Matay/AP Images

Distracted from the pain

After a tackle in the first half of a competitive game, Mohammed Ali Khan (here playing for BK Häcken in white) said he “had a bit of pain” but thought it was “just a bruise.” With his attention focused on the game, he played on. In the second half he was surprised to learn from an attending doctor that the leg was broken.

Social-Cultural Influences Pain is a product of our attention, our expectations, and also our culture (Gatchel et al., 2007; Reimann et al., 2010). Not surprisingly, then, our perception of pain varies with our social situation and our cultural traditions. We tend to perceive more pain when others seem to be experiencing pain (Symbaluk et al., 1997). This may help explain the apparent social aspects of pain, as when groups of Australian keyboard operators during the mid-1980s suffered outbreaks of severe pain while typing or performing other repetitive work—without any discernible physical abnormalities (Gawande, 1998). Sometimes the pain in sprain is mainly in the brain—literally. When people felt empathy for another’s pain, their own brain activity partly mirrored the activity of the actual brain in pain (Singer et al., 2004).

CONTROLLING PAIN If pain is where body meets mind—if it is both a

physical and a psychological phenomenon—then it should be treatable both physically and psychologically. Depending on the symptoms, pain control therapies may include drugs, surgery, acupuncture, electrical stimulation, massage, exercise, hypnosis, relaxation training, meditation, and thought distraction.

When in pain, we also benefit from our own built-in pain controls. Our brain releases a natural painkiller—*endorphins*—in response to severe pain or even vigorous exercise. Thus, when we are distracted from pain and soothed by endorphin release, the pain we experience may be greatly reduced. Sports injuries may go unnoticed until the after-game shower. People who carry a gene that boosts the availability of endorphins are less bothered by pain, and their brain is less responsive to pain (Zubieta et al., 2003). Others, who carry a mutated gene that disrupts pain circuit neurotransmission, may be unable to experience pain (Cox et al., 2006). Such discoveries point the way toward future pain medications that mimic these genetic effects.

Acupuncture: A jab well done

This acupuncturist is attempting to help this woman gain relief from back pain by using needles on points of the patient's hand.

Placebos Even *placebos* can help, by dampening the central nervous system's attention and responses to painful experiences—mimicking painkilling drugs (Eippert et al., 2009; Wager & Atlas, 2013). After being injected in the jaw with a stinging saltwater solution, men in one experiment received a placebo they had been told would relieve the pain. It did—they immediately felt better. “Nothing” worked. The men's belief in the fake painkiller triggered their brain to respond by dispensing endorphins, as revealed by activity in an area that releases natural painkilling opiates (Scott

et al., 2007; Zubieta et al., 2005). “Believing becomes reality,” noted one commentator (Thernstrom, 2006), as “the mind unites with the body.”

Another experiment pitted two placebos—fake pills and pretend acupuncture—against each other (Kaptchuk et al., 2006). People with persistent arm pain received either sham acupuncture (with trick needles that retracted without puncturing the skin) or blue cornstarch pills that looked like a medication often prescribed for strain injury. After two months, both groups were reporting less pain, with the fake acupuncture group reporting the greater pain drop. A quarter of those receiving the nonexistent needle pricks and 31 percent of those receiving the fake pills even complained of side effects, such as painful skin or dry mouth and fatigue.

Distraction Have you ever had a health care professional suggest that you focus on a pleasant image (“*Think of a warm, comfortable environment*”) or perform some task (“*Count backward by 3’s*”)? Drawing attention away from the painful stimulation is an effective way to activate brain pathways that inhibit pain and increase pain tolerance (Edwards et al., 2009). For burn victims receiving excruciating wound care, an even more effective distraction is escaping into a computer-generated 3-D world. Functional MRI (fMRI) scans have revealed that playing in the virtual reality reduces the brain’s pain-related activity (Hoffman, 2004). Because pain is in the brain, diverting the brain’s attention may bring relief.

Hypnosis Better yet, research suggests, maximize pain relief by combining a placebo with distraction (Buhle et al., 2012) and amplifying their effects with [hypnosis](#). Imagine you are about to be hypnotized. The hypnotist invites you to sit back, fix your gaze on a spot high on the wall, and relax. You hear a quiet, low voice suggest, “Your eyes are growing tired. . . . Your eyelids are becoming heavy . . . now heavier and heavier. . . . They are beginning to close. . . . You are becoming more deeply relaxed. . . . Your breathing is now deep and regular. . . . Your muscles are becoming more and more relaxed. Your whole body is beginning to feel like lead.” After a few minutes of this *hypnotic induction*, you may experience hypnosis. Words will have changed your brain.

hypnosis a social interaction in which one person (the hypnotist) suggests to another (the subject) that certain perceptions, feelings, thoughts, or behaviors

will spontaneously occur.

“Pain is increased by attending to it.”

Charles Darwin, *The Expression of the Emotions in Man and Animals*, 1872

Dissociation or social influence?

This hypnotized woman being tested by famous researcher Ernest Hilgard showed no pain when her arm was placed in an ice bath. But asked to press a key if some part of her felt the pain, she did so. To Hilgard (1986, 1992), this was evidence of dissociation, or divided consciousness. The social influence perspective, however, maintains that people responding this way are caught up in playing the role of “good subject.”

Hypnotists have no magical mind-control power; they merely focus people’s attention on certain images or behaviors. To some extent, we are all open to suggestion. But highly hypnotizable people—such as the 20 percent who can carry out a suggestion not to react to an open bottle of smelly ammonia—are especially suggestible and imaginative (Barnier & McConkey, 2004; Silva & Kirsch, 1992). Their brains also display altered activity when under hypnosis (Jiang et al., 2016).

Can hypnosis relieve pain? Yes. When unhypnotized people put their arm in an ice bath, they felt intense pain within 25 seconds (Elkins et al., 2012; Jensen, 2008). When hypnotized people did the same after being given suggestions to feel no pain, they indeed reported feeling little pain. As some dentists know, light hypnosis can reduce fear, thus reducing hypersensitivity to pain. Hypnosis has also lessened some forms of chronic and disability-related pain (Adachi et al., 2014; Bowker & Dorstyn, 2016).

In surgical experiments, hypnotized patients have required less medication, recovered sooner, and left the hospital earlier than unhypnotized control patients (Askay & Patterson, 2007; Hammond, 2008; Spiegel, 2007). Nearly 10 percent of us can become so deeply hypnotized that even major surgery can be performed without anesthesia. Half of us can gain at least some pain relief from hypnosis. The surgical use of hypnosis has flourished in Europe, where one Belgian medical team has performed more than 5000 surgeries with a combination of hypnosis, local anesthesia, and a mild sedative (Song, 2006).

Psychologists have proposed two explanations for how hypnosis works:

- *Social influence theory* contends that hypnosis is a by-product of normal social and mental processes (Lynn et al., 1990; Spanos & Coe, 1992). In this view, hypnotized people, like actors caught up in a role, begin to feel

and behave in ways appropriate for “good hypnotic subjects.” They may allow the hypnotist to direct their attention and fantasies away from pain.

- *Dissociation theory* proposes that hypnosis is a special dual-processing state of **dissociation**—a split between different levels of consciousness. Dissociation theory seeks to explain why, when no one is watching, previously hypnotized people may carry out **posthypnotic suggestions** (which are made during hypnosis but carried out after the person is no longer hypnotized) (Perugini et al., 1998). It also offers an explanation for why people hypnotized for pain relief may show brain activity in areas that receive sensory information, but not in areas that normally process pain-related information (Rainville et al., 1997).

dissociation a split in consciousness, which allows some thoughts and behaviors to occur simultaneously with others.

posthypnotic suggestion a suggestion, made during a hypnosis session, to be carried out after the subject is no longer hypnotized; used by some clinicians to help control undesired symptoms and behaviors.

Selective attention may also play a role in hypnotic pain relief. Brain scans show that hypnosis increases activity in frontal lobe attention systems (Oakley & Halligan, 2013). So, while hypnosis does not block sensory input itself, it may block our attention to those stimuli. This helps explain why injured soldiers, caught up in battle, may feel little or no pain until they reach safety.

Taste

LOQ 6-21 In what ways are our senses of taste and smell similar, and how do they differ?

Like touch, our sense of taste involves several basic sensations. Taste’s sensations were once thought to be *sweet*, *sour*, *salty*, and *bitter*, with all others stemming from mixtures of these four (McBurney & Gent, 1979). Then, as investigators searched for specialized nerve fibers for the four taste sensations, they encountered a receptor for what we now know is a fifth—the savory, meaty taste of *umami*, best experienced as the flavor enhancer monosodium glutamate (MSG).

Lauren Burke/Getty Images

Tastes exist for more than our pleasure (see [TABLE 6.2](#)). Pleasureful tastes attracted our ancestors to energy- or protein-rich foods that enabled their survival. Aversive tastes deterred them from new foods that might be toxic. We see the inheritance of this biological wisdom in today's 2- to 6-year-olds, who are typically fussy eaters, especially when offered new meats or bitter-tasting vegetables, such as spinach and brussels sprouts (Cooke et al., 2003). Meat and plant toxins were both potentially dangerous sources of food poisoning for our ancestors, especially children. Given repeated small tastes of disliked new foods, however, most children begin to accept them (Wardle et al., 2003). We come to like what we eat. Compared with breast-fed babies, German babies bottle-fed vanilla-flavored milk grew up to be adults with a striking preference for vanilla flavoring (Haller et al., 1999). The taste-exposure phenomenon even extends to the womb. In one experiment, babies whose mothers drank carrot juice during the end of pregnancy and the early weeks of nursing developed a liking for carrot-flavored cereal (Mennella et al., 2001).

TABLE 6.2

The Survival Functions of Basic Tastes

Taste	Indicates
<i>Sweet</i>	Energy source
<i>Salty</i>	Sodium essential to physiological processes
<i>Sour</i>	Potentially toxic acid
<i>Bitter</i>	Potential poisons
<i>Umami</i>	Proteins to grow and repair tissue

Taste is a chemical sense. Inside each little bump on the top and sides of your tongue are 200 or more taste buds, each containing a pore that catches food chemicals. In each taste bud pore, 50 to 100 taste receptor cells project antenna-like hairs that sense food molecules. Some receptors respond mostly to sweet-tasting molecules, others to salty-, sour-, umami-, or bitter-tasting ones. Each receptor transmits its message to a matching partner cell in your brain's temporal lobe (Barretto et al., 2015). Some people have more taste buds than others, enabling them to experience more intense tastes. These “supertasters” can also taste some things that the rest of us cannot (Bartoshuk, 2000).

It doesn't take much to trigger a taste response. If a stream of water is pumped across your tongue, the addition of a concentrated salty or sweet taste for but one-tenth of a second will get your attention (Kelling & Halpern, 1983). When a friend asks for “just a taste” of your soft drink, you can squeeze off the straw after a mere instant.

Taste receptors reproduce themselves every week or two, so if you burn your tongue it hardly matters. However, as you grow older, the number of taste buds decreases, as does taste sensitivity (Cowart, 1981). (No wonder adults enjoy strong-tasting foods that children resist.) Smoking and alcohol use accelerate these declines. Those who have lost their sense of taste have reported that food tastes like “straw” and is hard to swallow (Cowart, 2005).

There's more to taste than meets the tongue. Expectations can influence taste. When told a sausage roll was “vegetarian,” nonvegetarian people

judged it decidedly inferior to its identical partner labeled “meat” (Allen et al., 2008). In another experiment, hearing that a wine cost \$90 rather than its real \$10 price made it taste better and triggered more activity in a brain area that responds to pleasant experiences (Plassmann et al., 2008). Contrary to Shakespeare’s presumption (in *Romeo and Juliet*) that “A rose by any other name would smell as sweet,” labels matter. And speaking of smell . . .

Smell

Inhale, exhale. Between birth’s first inhale and death’s last exhale, about 500 million breaths of life-sustaining air will bathe your nostrils in a stream of scent-laden molecules. The resulting experience of smell (**olfaction**) is strikingly intimate. With every breath, you inhale something of whatever or whoever it is you smell.

Smell, like taste, is a chemical sense. We smell something when molecules of a substance carried in the air reach a tiny cluster of receptor cells at the top of each nasal cavity (**FIGURE 6.40**). These 20 million olfactory receptors, waving like sea anemones on a reef, respond selectively—to the aroma of a cake baking, to a wisp of smoke, to a friend’s fragrance. Instantly, they alert the brain through their axon fibers.

FIGURE 6.40 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 6.40 The sense of smell

If you are to smell a flower, airborne molecules of its fragrance must reach receptors at the top of your nose. Sniffing swirls air up to the receptors, enhancing the aroma. The receptor cells send messages to

the brain's olfactory bulb, and then onward to the temporal lobe's primary smell cortex and to the parts of the limbic system involved in memory and emotion.

Impress your friends with your new word for the day: People unable to see are said to experience blindness. People unable to hear experience deafness. People unable to smell experience *anosmia*. The 1 in 7500 people born with anosmia not only have trouble cooking and eating, but also are somewhat more prone to depression, accidents, and relationship insecurity (Croy et al., 2012, 2013).

Being part of an old, primitive sense, olfactory neurons bypass the brain's sensory control center, the thalamus. Eons before our cerebral cortex had fully evolved, our mammalian ancestors sniffed for food—and for predators. They also smelled molecules called *pheromones*, secreted by other members of their species. Some pheromones serve as sexual attractants.

Odor molecules come in many shapes and sizes—so many, in fact, that it takes many different receptors to detect them. A large family of genes designs the 350 or so receptor proteins that recognize particular odor molecules (Miller, 2004). Linda Buck and Richard Axel (1991) discovered (in work for which they received a 2004 Nobel Prize) that these receptor proteins are embedded on the surface of nasal cavity neurons. As a key slips into a lock, so odor molecules slip into these receptors. Yet we don't seem to have a distinct receptor for each detectable odor. Odors trigger combinations of receptors, in patterns that are interpreted by the olfactory cortex. As the English alphabet's 26 letters can combine to form many words, so odor molecules bind to different receptor arrays, producing at least 1 trillion odors that we could potentially discriminate (Bushdid et al., 2014). It is the combinations of olfactory receptors, which activate different neuron patterns, that allow us to distinguish between the aromas of fresh-brewed and hours-old coffee (Zou et al., 2005).

For an animated explanation of how we smell, engage online with **Concept Practice: Sense of Smell**.

Animals that have many times more olfactory receptors than we do also use their sense of smell to communicate and to navigate. Long before a shark

can see its prey, or a moth its mate, olfactory cues direct their way, as they also do for migrating salmon returning to their home stream. After being exposed in a hatchery to one of two odorant chemicals, returning salmon will later seek whichever stream was spiked with the familiar smell (Barinaga, 1999).

LAYNE BAILEY/AP Images

The nose knows

Humans have some 20 million olfactory receptors. A bloodhound has 220 million (Herz, 2007).

Aided by smell, a mother fur seal returning to a beach crowded with pups will find her own. Human mothers and nursing infants also quickly learn to recognize each other's scents (McCarthy, 1986). As any dog or cat with a good nose could tell us, we each have our own identifiable chemical signature. (One noteworthy exception: A dog will follow the tracks of one identical twin as though they had been made by the other [Thomas, 1974].)

The brain knows what the nose doesn't like (Zou et al., 2016). But a smell's appeal—or lack of it—also depends on cultural experiences (Herz, 2001). In the United States, people associate the smell of wintergreen with candy and gum, and they tend to like it. In Great Britain, wintergreen often is associated with medicine, and people find it less appealing. Odors also evoked unpleasant emotions when researchers frustrated Brown University students with a rigged computer game in a scented room (Herz et al., 2004).

Later, if exposed to the same odor while working on a verbal task, the students' frustration was rekindled and they gave up sooner than others exposed to a different odor or no odor.

Important as our sense of smell is, it is less acute than our senses of seeing and hearing. Looking out across a garden, we see its forms and colors in exquisite detail and hear a variety of birds singing, yet we smell little of it without sticking our nose into the blossoms. Compared with how we experience and remember sights and sounds, smells are primitive and harder to describe and recall (Richardson & Zucco, 1989; Zucco, 2003). Test it yourself: Which is easier, describing the *sound* of coffee brewing, or the *aroma* of coffee? For most people, it's the sound.

Although we also have trouble recalling odors by name, we have a remarkable capacity to recognize long-forgotten odors and their associated memories (Engen, 1987; Schab, 1991). The smell of the sea, the scent of a perfume, or an aroma of a favorite relative's kitchen can bring to mind a happy time. Our brain's circuitry helps explain an odor's power to evoke feelings and memories ([FIGURE 6.41](#)). A hotline runs between the brain area receiving information from the nose and the brain's ancient limbic centers associated with memory and emotion. Thus, when put in a foul-smelling room, people expressed harsher judgments of other people and of immoral acts (such as lying or keeping a found wallet) (Inbar et al., 2011; Schnall et al., 2008). Exposed to a fishy smell, people become more suspicious (Lee, D. S., et al., 2015). And when riding on a train car with the citrus scent of a cleaning product, people have left behind less trash (de Lange et al., 2012).

FIGURE 6.41 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 6.41 Taste, smell, and memory

Information from the taste buds (yellow arrow) travels to an area between the frontal and temporal lobes of the brain. It registers in an area not far from where the brain receives information from our sense of smell, which interacts with taste. The brain's circuitry for smell (red area) also connects with areas involved in memory storage, which helps explain why a smell can trigger a memory.

Gender and age influence our ability to identify scents. Women and young adults have the best sense of smell (Wickelgren, 2009; Wysocki & Gilbert, 1989). Physical condition also matters. Smokers and people with Alzheimer's disease, Parkinson's disease, or alcohol use disorder typically have a diminished sense of smell (Doty, 2001). For all of us, however, the sense of smell tends to peak in early adulthood and gradually declines thereafter.

“There could be a stack of truck tires burning in the living room, and I wouldn't necessarily smell it. Whereas my wife can detect a lone spoiled grape two houses away.”

Dave Barry, 2005

RETRIEVAL PRACTICE

RP-18 How does our system for sensing smell differ from our

sensory systems for touch and taste?

ANSWER: We have four basic touch senses and five taste sensations. But we have no specific smell receptors. Instead, different combinations of odor receptors send messages to the brain, enabling us to recognize some 1 trillion different smells.

Body Position and Movement

LOQ 6-22 How do we sense our body's position and movement?

Without sensing your body's position and movement, you could not put food in your mouth, stand up, or reach out and touch someone. Nor could you perform the “simple” act of taking one step forward. That act requires feedback from, and instructions to, some 200 muscles, and it engages brain power that exceeds the mental activity involved in reasoning. Like all your other voluntary movements, taking a step is possible because of your sense of [kinesthesia](#), which keeps you aware of your body parts' position and movement. You came equipped with millions of position and motion sensors in muscles, tendons, and joints all over your body. These sensors provide constant feedback to your brain. Twist your wrist one degree and your brain receives an immediate update.

kinesthesia [kin-ehs-THEE-zhuh] the system for sensing the position and movement of individual body parts.

You can momentarily imagine being without sight and sound. Close your eyes and plug your ears, and experience the dark silence. But what would it be like to live without touch or kinesthesia—without being able to sense the positions of your limbs when you wake during the night? Ian Waterman of Hampshire, England, knows. In 1972, at age 19, Waterman contracted a rare viral infection that destroyed the nerves enabling his sense of light touch and of body position and movement. People with this condition report feeling disembodied, as though their body is dead, not real, not theirs (Sacks, 1985). With prolonged practice, Waterman learned to walk and eat—by visually

focusing on his limbs and directing them accordingly. But if the lights went out, he would crumple to the floor (Azar, 1998).

© Robert Kanavel

Bodies in space

Each of these high school competitive cheer team members can thank her inner ears for the information that enables her brain to monitor her body's position so expertly.

Vision interacts with kinesthesia for you, too. Stand with your right heel in front of your left toes. Easy. Now close your eyes and try again. Did you wobble?

A companion [vestibular sense](#) monitors your head's (and thus your body's) position and movement. The biological gyroscopes for this sense of equilibrium are two structures in your inner ear. The first, your fluid-filled *semicircular canals*, look like a three-dimensional pretzel (see [Figure 6.35a](#)). The second structure is the pair of calcium crystal-filled *vestibular sacs*. When your head rotates or tilts, the movement of these organs stimulates hair-like receptors, which send nerve signals to your cerebellum at the back of your brain, enabling you to sense your body position and maintain your balance.

vestibular sense the sense of body movement and position, including the sense of balance.

If you twirl around and then come to an abrupt halt, neither the fluid in your semicircular canals nor your kinesthetic receptors will immediately return to their neutral state. The dizzy aftereffect fools your brain with the sensation that you're still spinning. This illustrates a principle that underlies perceptual illusions: Mechanisms that normally give us an accurate experience of the world can, under special conditions, fool us. Understanding how we get fooled provides clues to how our perceptual system works.

RETRIEVAL PRACTICE

RP-19 Where are the kinesthetic receptors and the vestibular sense receptors located?

ANSWER: Kinesthetic receptors are located in our joints, tendons, and muscles. Vestibular sense receptors are located in our inner ear.

One little known fact about your vestibular sense: It is super speedy. If you slip, your vestibular sensors automatically and instantly order your skeletal response, well before you have consciously decided how to right yourself.

Try this: Hold one of your thumbs in front of your face then move it rapidly right to left and back. Notice how your thumb blurs (your vision isn't fast enough to track it). Now hold your thumb still and swivel your head from left to right. Voilà! Your thumb stays clear—because your vestibular system, which is monitoring your head position, speedily moves the eyes. Head moves right, eyes move left. Vision is fast, but the vestibular sense is faster.

Sensory Interaction

LOQ 6-23 How does sensory interaction influence our perceptions,

and what is *embodied cognition*?

We have seen that vision and kinesthesia interact. Actually, none of our senses act alone. All our senses—seeing, hearing, tasting, smelling, touching—eavesdrop on one another and our brain blends their inputs to interpret the world (Rosenblum, 2013). This is [sensory interaction](#) at work. One sense can influence another.

sensory interaction the principle that one sense may influence another, as when the smell of food influences its taste.

Consider how smell sticks its nose into the business of taste. Hold your nose, close your eyes, and have someone feed you various foods. A slice of apple may be indistinguishable from a chunk of raw potato. A piece of steak may taste like cardboard. Without their smells, a cup of cold coffee may be hard to distinguish from a glass of red wine. A big part of taste is right under your nose.

Thus, to savor a taste, we normally breathe the aroma through our nose. Like smoke rising in a chimney, food molecules rise into our nasal cavity. This is why food tastes bland when you have a bad cold. Smell can also change our perception of taste: A drink's strawberry odor enhances our perception of its sweetness. Even touch can influence our taste. Depending on its texture, a potato chip "tastes" fresh or stale (Smith, 2011). Smell + texture + taste = flavor. Yet perhaps you have noticed: Despite smell's contribution, flavor feels located in the mouth, not the nose (Stevenson, 2014).

Vision and hearing may similarly interact. A weak flicker of light that we have trouble perceiving becomes more visible when accompanied by a short burst of sound (Kayser, 2007). The reverse is also true: We can hear soft sounds more easily if they are paired with a visual cue. If I [DM], as a person with hearing loss, watch a video with on-screen captions, I have no trouble hearing the words I am seeing. But if I then decide I don't need the captions and turn them off, I will quickly realize I do need them. The eyes guide the ears ([FIGURE 6.42](#)).

FIGURE 6.42 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
© Albrecht Weisser/Westend61/Corbis

FIGURE 6.42 Sensory interaction

Seeing the speaker forming the words, which Apple's FaceTime video-chat feature allows, makes those words easier to understand for hard-of-hearing listeners (Knight, 2004).

So our senses do not function in isolation; they interact. But what happens if they disagree? What if our eyes see a speaker form one sound but our ears *hear* another sound? Surprise: Our brain may perceive a third sound that blends both inputs. Seeing mouth movements for *ga* while hearing *ba*, we may perceive *da*. This phenomenon is known as the *McGurk effect*, after Scottish psychologist Harry McGurk, who, with his assistant John MacDonald, discovered the effect (1976). For all of us, lip reading is part of hearing.

We have seen that our perceptions have two main ingredients: Our bottom-up sensations and our top-down cognitions (such as expectations, attitudes, thoughts, and memories). In everyday life, sensation and perception are two points on a continuum. It's not surprising, then, that the brain circuits processing our physical sensations sometimes interact with brain circuits responsible for cognition. The result is **embodied cognition**. We think from within a body. Some examples from playful experiments:

embodied cognition the influence of bodily sensations, gestures, and other states on cognitive preferences and judgments.

- *Physical warmth may promote social warmth.* After holding a warm drink rather than a cold one, people were more likely to rate someone more warmly, feel closer to them, and behave more generously (IJzerman & Semin, 2009; Williams & Bargh, 2008). Have hot tea with José and iced tea with his identical twin Juan, and you may perceive José to be the warmer brother.
- *Social exclusion can literally feel cold.* After being given the cold shoulder by others, people judged the room to be colder than did those who had been treated warmly (Zhong & Leonardelli, 2008).
- *Judgments of others may also mimic body sensations.* Sitting at a wobbly desk and chair makes others' relationships, or even one's own romantic relationship, seem less stable (Forest et al., 2015; Kille et al., 2013).

Are you wondering how researchers test these kinds of questions? Engage online with **Immersive Learning: How Would You Know If a Cup of Coffee Can Warm Up Relationships?**

As we attempt to decipher our world, our brain blends inputs from multiple channels. But in a few select individuals, the brain circuits for two or more senses become joined in a phenomenon called *synesthesia*, where the stimulation of one sense (such as hearing sound) triggers an experience of another (such as seeing color). Early in life, “exuberant neural connectivity” produces some arbitrary associations among the senses, which later are normally—but not always—pruned (Wagner & Dobkins, 2011). Thus, hearing music may activate color-sensitive cortex regions and trigger a sensation of color (Brang et al., 2008; Hubbard et al., 2005). Seeing the number 3 may evoke a taste or color sensation (Newell & Mitchell, 2016). Those who experience such sensory shifts are known as *synesthetes*.

* * *

For a summary of our sensory systems, see [TABLE 6.3](#).

TABLE 6.3

Summarizing the Senses

Sensory System	Source	Receptors	Key Brain Areas
<i>Vision</i>	Light waves striking the eye	Rods and cones in the retina	Occipital lobes
<i>Hearing</i>	Sound waves striking the outer ear	Cochlear hair cells in the inner ear	Temporal lobes
<i>Touch</i>	Pressure, warmth, cold, harmful chemicals	Receptors (including pain-sensitive <i>nociceptors</i>), mostly in the skin, which detect pressure, warmth, cold, and pain	Somatosensory cortex
<i>Taste</i>	Chemical molecules in the mouth	Basic tongue receptors for sweet, sour, salty, bitter, and umami	Frontal temporal lobe border
<i>Smell</i>	Chemical molecules breathed in through the nose	Millions of receptors at top of nasal cavities	Olfactory bulb
<i>Body position— kinesthesia</i>	Any change in position of a body part, interacting with vision	Kinesthetic sensors in joints, tendons, and muscles	Cerebellum
<i>Body movement—</i>	Movement of fluids in the inner ear	Hair-like receptors in the ears' semicircular canals and vestibular	Cerebellum

<i>vestibular sense</i>	caused by head/body movement	sacs

ESP—Perception Without Sensation?

LOQ 6-24 What are the claims of *ESP*, and what have most research psychologists concluded after putting these claims to the test?

The river of perception is fed by sensation, cognition, and emotion. If perception is the product of these three sources, what can we say about extrasensory perception (ESP), which claims that perception can occur apart from sensory input? Are there indeed people—any people—who can read minds, see through walls, or foretell the future? Nearly half of Americans have agreed there are (AP, 2007; Moore, 2005).

extrasensory perception (ESP) the controversial claim that perception can occur apart from sensory input; includes telepathy, clairvoyance, and

precognition.

Do you think you might have ESP? Engage online with **Assess Your Strengths: ESP and Critical Thinking**.

If ESP is real, we would need to overturn the scientific understanding that we are creatures whose minds are tied to our physical brains and whose perceptual experiences of the world are built of sensations. The most testable and, for this discussion, most relevant ESP claims are

- *telepathy*: mind-to-mind communication.
- *clairvoyance*: perceiving remote events, such as a house on fire in another state.
- *precognition*: perceiving future events, such as an unexpected death in the next month.

Closely linked is *psychokinesis*, or “mind moving matter,” such as levitating a table or influencing the roll of a die. (The claim is illustrated by the wry request, “Will all those who believe in psychokinesis please raise my hand?”)

Most research psychologists and scientists have been skeptical that paranormal phenomena exist. But in several reputable universities, **parapsychology** researchers perform scientific experiments searching for possible ESP phenomena (Storm et al., 2010a,b; Turpin, 2005). Before seeing how they conduct their research, let’s consider some popular beliefs.

parapsychology the study of paranormal phenomena, including ESP and psychokinesis.

BIZARRO © 2014 Dan Piraro, Dist. By King Features

Premonitions or Pretensions?

Can psychics see into the future? Although one might wish for a psychic stock forecaster, the tallied forecasts of “leading psychics” reveal meager accuracy. During the 1990s, the tabloid psychics were all wrong in predicting surprising events. (Madonna did not become a gospel singer, the Statue of Liberty did not lose both its arms in a terrorist blast, Queen Elizabeth did not abdicate her throne to enter a convent.) And the psychics have missed big-news events. Where were the psychics on 9/10 when we needed them? Why, despite a \$50 million reward, could no psychics help locate Osama bin Laden after 9/11? And why, when the Chilean government consulted four psychics after a mine collapse trapped 33 miners in 2010, did those psychics sorrowfully decide “They’re all dead” (Kraul, 2010)? Imagine their surprise when all 33 miners were rescued 69 days later.

After Amanda Berry went missing in Cleveland in 2003, her distraught and desperate mother turned to a famed TV psychic for answers. “She’s not alive, honey,” the psychic told the devastated mom, who died without living to see her daughter rescued in 2013 (Radford, 2013). According to one analysis, this result brought that psychic’s record on 116 missing person and death cases to 83 unknown outcomes, 33 incorrect, and zero mostly correct. To researcher Ryan Shaffer (2013), that’s the record of a “psychic defective.”

The psychic visions offered to police departments have been no more accurate than guesses made by others (Nickell, 1994, 2005; Radford, 2010; Reiser, 1982). But their sheer volume does increase the odds of an occasional correct guess, which psychics can then report to the media. Such visions can sound amazingly correct when later retrofitted to match events. Nostradamus, a sixteenth-century French psychic, explained in an unguarded moment that his ambiguous prophecies “could not possibly be understood till they were interpreted after the event and by it.”

“To be sure of hitting the target, shoot first and call whatever you hit the target.”

Writer-artist Ashleigh Brilliant

Are everyday people’s “visions” any more accurate than the psychics’ predictions? Do our dreams foretell the future, or do they only seem to do so when we recall or reconstruct them in light of what has already happened? Are our remembered visions merely revisions? After famed aviator Charles Lindbergh’s baby son was kidnapped and murdered in 1932, but before the body was discovered, two Harvard psychologists invited people to report their dreams about the child (Murray & Wheeler, 1937). How many visionaries replied? 1300. How many accurately envisioned the child dead? Five percent. How many also correctly anticipated the body’s location—buried among trees? Only 4. Although this number was surely no better than chance, to those 4 dreamers, the accuracy of their apparent precognitions must have seemed uncanny.

“A person who talks a lot is sometimes right.”

Spanish proverb

Given the countless events in the world each day, and given enough days, some stunning coincidences are bound to occur. By one careful estimate, chance alone would predict that more than a thousand times per day, someone on Earth will think of another person and then, within the next five minutes, learn of that person’s death (Charpak & Broch, 2004). Thus, when explaining an astonishing event, we should “give chance a chance”

(Lilienfeld, 2009). With enough time and people, the improbable becomes inevitable.

Putting ESP to Experimental Test

When faced with claims of mind reading or out-of-body travel or communication with the dead, how can we separate fiction from strange-but-true fact? At the heart of science is a simple answer: *Test them to see if they work*. If they do, so much the better for the ideas. If they don't, so much the better for our skepticism.

Both believers and skeptics agree that what parapsychology needs is a reproducible phenomenon and a theory to explain it. Parapsychologist Rhea White (1998) spoke for many in saying that “the image of parapsychology that comes to my mind, based on nearly 44 years in the field, is that of a small airplane [that] has been perpetually taxiing down the runway of the Empirical Science Airport since 1882 . . . its movement punctuated occasionally by lifting a few feet off the ground only to bump back down on the tarmac once again. It has never taken off for any sustained flight.”

Courtesy of Claire Cole

Testing psychic powers in the British population

Psychologists created a “mind machine” to see if people could influence or predict a coin toss (Wiseman & Greening, 2002). Using a touch-sensitive screen, visitors to British festivals were given four attempts to call heads or tails, playing against a computer that kept score. By the time the experiment ended, nearly 28,000 people had predicted 110,959

tosses—with 49.8 percent correct.

How might we test ESP claims in a controlled, reproducible experiment? An experiment differs from a staged demonstration. In the laboratory, the experimenter controls what the “psychic” sees and hears. On stage, the psychic controls what the audience sees and hears.

Daryl Bem, a respected social psychologist, once quipped that “a psychic is an actor playing the role of a psychic” (1984). Yet this one-time skeptic reignited hopes for replicable evidence of ESP with nine experiments that seemed to show people anticipating future events (Bem, 2011). In one, when an erotic scene was about to appear on a screen in one of two randomly selected positions, Cornell University participants guessed the right placement 53.1 percent of the time (beating 50 percent by a small but statistically significant margin). Bem wondered if his “anomalous” findings reflected an evolutionary advantage to those who can precognitively anticipate future dangers.

Despite the paper having survived critical reviews by a top-tier journal, critics scoffed. Some found the methods “badly flawed” (Alcock, 2011) or the statistical analyses “biased” (Wagenmakers et al., 2011). Others predicted the results could not be replicated by “independent and skeptical researchers” (Helfand, 2011). And still others had more sweeping objections: “If any of his claims were true,” wrote one cognitive scientist, “then all of the bases underlying contemporary science would be toppled, and we would have to rethink everything about the nature of the universe” (Hofstadter, 2011).

Anticipating such skepticism, Bem has made his research materials available to anyone who wishes to replicate his studies. Multiple attempts have met with minimal success and continuing controversy (Bem et al., 2014; Galak et al., 2012; Ritchie et al., 2012; Wagenmakers, 2014). Regardless, science is doing its work:

- It has been open to a finding that challenges its own assumptions.
- Through follow-up research, it has assessed the validity of that finding.

And that is how science sifts crazy-sounding ideas, leaving most on the historical waste heap while occasionally surprising us.

“At the heart of science is an essential tension between two seemingly contradictory attitudes—an openness to new ideas, no matter how bizarre or counterintuitive they may be, and the most ruthless skeptical scrutiny of all ideas, old and new.”

Carl Sagan (1987)

For nineteen years, one skeptic, magician James Randi, offered \$1 million “to anyone who proves a genuine psychic power under proper observing conditions” (Randi, 1999; Thompson, 2010). French, Australian, and Indian groups have made similar offers of up to 200,000 euros (CFI, 2003). Large as these sums are, the scientific seal of approval would be worth far more. To refute those who say there is no ESP, one need only produce a single person who can demonstrate a single, reproducible ESP event. (To refute those who say pigs can’t talk would take but one talking pig.) So far, no such person has emerged.

RETRIEVAL PRACTICE

RP-20 If an ESP event occurred under controlled conditions, what would be the next best step to confirm that ESP really exists?

ANSWER: The ESP event would need to be reproduced in other scientific studies.

* * *

To feel awe, mystery, and a deep reverence for life, we need look no further than our own perceptual system and its capacity for organizing formless nerve impulses into colorful sights, vivid sounds, and evocative smells. As Shakespeare’s Hamlet recognized, “There are more things in Heaven and Earth, Horatio, than are dreamt of in your philosophy.” Within our ordinary sensory and perceptual experiences lies much that is truly extraordinary—surely much more than has so far been dreamt of in our psychology.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The snail-shaped tube in the inner ear, where sound waves are converted into neural activity, is called the _____.

What are the basic steps in transforming sound waves into perceived sound?

_____ theory explains how we hear high-pitched sounds, and

_____ theory explains how we hear low-pitched sounds.

The sensory receptors that are found mostly in the skin and that detect hurtful temperatures, pressure, or chemicals are called _____.

The gate-control theory of pain proposes that

- a. special pain receptors send signals directly to the brain.
- b. pain is a property of the senses, not of the brain.
- c. small spinal cord nerve fibers conduct most pain signals, but large-fiber activity can close access to those pain signals.
- d. pain can often be controlled and managed effectively through the use of relaxation techniques.

How does the biopsychosocial approach explain our experience of pain? Provide examples.

We have specialized nerve receptors for detecting which five tastes? How did this ability aid our ancestors?

_____ is your sense of body position and movement. Your _____ specifically monitors your head's movement, with sensors in the inner ear.

Why do you feel a little dizzy immediately after a roller-coaster ride?

A food's aroma can greatly enhance its taste. This is an example of

- a. olfaction.
- b. synesthesia.
- c. kinesthesia.
- d. sensory interaction.

Which of the following ESP phenomena is supported by solid, replicable scientific evidence?

- a. Telepathy
- b. Clairvoyance
- c. Precognition
- d. None of these answers

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Learning by Observation

THINKING CRITICALLY ABOUT: The Effects of Viewing Media Violence

In the early 1940s, University of Minnesota graduate students Marian Breland and Keller Breland witnessed the power of a new learning technology. Their mentor, B. F. Skinner, would become famous for *shaping* rat and pigeon behaviors by delivering well-timed rewards as the animals inched closer and closer to a desired behavior. Impressed by Skinner's results, the Brelands began shaping the behavior of cats, chickens, parakeets, turkeys, pigs, ducks, and hamsters (Bailey & Gillaspy, 2005). They eventually formed Animal Behavior Enterprises and spent the next half-century training more than 15,000 animals from 140 species for movies, traveling shows, amusement parks, corporations, and the government.

While writing about animal trainers, journalist Amy Sutherland wondered if shaping had uses closer to home (2006a,b). If baboons could be trained to skateboard and elephants to paint, might “the same techniques . . . work on that stubborn but lovable species, the American husband”? To find out, she trained her husband, Scott. Step by step, she “began thanking Scott if he threw one dirty shirt into the hamper. If he threw in two, I’d kiss him [and] as he basked in my appreciation, the piles became smaller.” After two years of “thinking of my husband as an exotic animal species,” she reported, “my marriage is far smoother, my husband much easier to love.”

Like husbands and other animals, we learn from experience. Indeed, nature's most important gift may be our *adaptability*—our capacity to learn new behaviors that help us cope with our changing world. We can learn how to build grass huts or snow shelters, submarines or space stations, and thereby adapt to almost any environment.

Learning breeds hope. What is learnable we can potentially teach—a fact that encourages parents, educators, coaches, and animal trainers. What has been learned we can potentially change by new learning—an assumption that underlies counseling, psychotherapy, and rehabilitation programs. No matter how unhappy, or unsuccessful, or unloved we are, that need not be the end of our story.

No topic is closer to the heart of psychology than *learning*. In earlier chapters we considered infants' learning, and the learning of visual perceptions, of a drug's expected effect, and of gender roles. In later chapters we will see how learning shapes our thoughts and language, our motivations and emotions, our personalities and attitudes. Here in this chapter we

examine the heart of learning: classical conditioning, operant conditioning, the effects of biology and cognition on learning, and learning by observation.

Basic Learning Concepts and Classical Conditioning

How Do We Learn?

LOQ **LEARNING OBJECTIVE QUESTION** **7-1** How do we define *learning*, and what are some basic forms of learning?

By **learning**, we humans adapt to our environments. We learn to expect and prepare for significant events such as food or pain (*classical conditioning*). We learn to repeat acts that bring rewards and avoid acts that bring unwanted results (*operant conditioning*). We learn new behaviors by observing events and people, and through language, we learn things we have neither experienced nor observed (*cognitive learning*). But *how* do we learn?

learning the process of acquiring through experience new and relatively enduring information or behaviors.

More than 200 years ago, philosophers John Locke and David Hume echoed Aristotle's conclusion from 2000 years earlier: We learn, first, by *association*. Our minds naturally connect events that occur in sequence. Suppose you see and smell freshly baked bread, eat some, and find it satisfying. The next time you see and smell fresh bread, you will expect that eating it will again be satisfying. So, too, with sounds. If you associate a sound with a frightening consequence, hearing the sound alone may trigger your fear. As one 4-year-old exclaimed after watching a TV character get mugged, "If I had heard that music, I wouldn't have gone around the corner!" (Wells, 1981).

Learned associations often operate subtly:

- Give people a red pen (associated with error marking) rather than a black

pen and, when correcting essays, they will spot more errors and give lower grades (Rutchick et al., 2010).

- When voting, people are more likely to support taxes to aid education if their assigned voting place is in a school (Berger et al., 2008).

Learned associations also feed our habitual behaviors (Wood et al., 2014b). Habits can form when we repeat behaviors in a given context—sleeping in a certain posture in bed, biting our nails in class, eating popcorn in a movie theater. As behavior becomes linked with the context, our next experience of that context will evoke our habitual response. Especially when our willpower is depleted, as when we’re mentally fatigued, we tend to fall back on our habits (Neal et al., 2013). That’s true of both good habits (eating fruit) and bad (overindulging in alcohol) (Graybiel & Smith, 2014). To increase our self-control, and to connect our resolutions with positive outcomes, the key is forming “beneficial habits” (Galla & Duckworth, 2015).

How long does it take to form a beneficial habit? To find out, one British research team asked 96 university students to choose some healthy behavior (such as running before dinner or eating fruit with lunch), to do it daily for 84 days, and to record whether the behavior felt automatic (something they did without thinking and would find it hard not to do). On average, behaviors became habitual after about 66 days (Lally et al., 2010). Is there something you’d like to make a routine or essential part of your life? Just do it every day for two months, or a bit longer for exercise, and you likely will find yourself with a new habit. This happened for both of us—with a midday workout [DM] or late afternoon run [ND] having long ago become an automatic daily routine.

“Watch your thoughts, they become words;
watch your words, they become actions;
watch your actions, they become habits;
watch your habits, they become character;
watch your character, for it becomes your destiny.”

Attributed to Frank Outlaw, 1977

Other animals also learn by association. Disturbed by a squirt of water, the

sea slug *Aplysia* protectively withdraws its gill. If the squirts continue, as happens naturally in choppy water, the withdrawal response diminishes. But if the sea slug repeatedly receives an electric shock just after being squirted, its protective response to the squirt instead grows stronger. The animal has associated the squirt with the impending shock.

Complex animals can learn to associate their own behavior with its outcomes. An aquarium seal will repeat behaviors, such as slapping and barking, that prompt people to toss it a herring.

By linking two events that occur close together, both sea slugs and seals are exhibiting **associative learning**. The sea slug associates the squirt with an impending shock; the seal associates slapping and barking with a herring treat. Each animal has learned something important to its survival: anticipating the immediate future.

associative learning learning that certain events occur together. The events may be two stimuli (as in classical conditioning) or a response and its consequence (as in operant conditioning).

This process of learning associations is *conditioning*. It takes two main forms:

- In *classical conditioning*, we learn to associate two stimuli and thus to anticipate events. (A **stimulus** is any event or situation that evokes a response.) We learn that a flash of lightning signals an impending crack of thunder; when lightning flashes nearby, we start to brace ourselves (**FIGURE 7.1**). We associate stimuli that we do not control, and we respond automatically (exhibiting **respondent behavior**).
- In *operant conditioning*, we learn to associate a response (our behavior) and its consequence. Thus we (and other animals) learn to repeat acts followed by good results (**FIGURE 7.2**) and avoid acts followed by bad results. These associations produce **operant behaviors** (which operate on the environment to produce a consequence).

stimulus any event or situation that evokes a response.

respondent behavior behavior that occurs as an automatic response to some stimulus.

operant behavior behavior that operates on the environment, producing consequences.

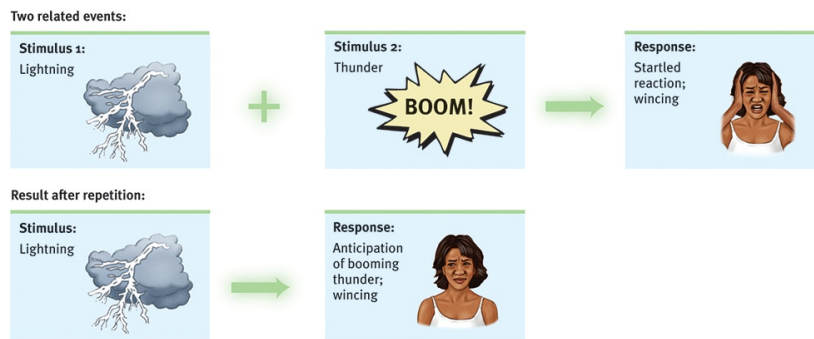

FIGURE 7.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.1 Classical conditioning

FIGURE 7.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.2 Operant conditioning

Most of us would be unable to name the order of the songs on our favorite album or playlist. Yet, hearing the end of one piece cues (by association) an anticipation of the next. Likewise, when singing your national anthem, you associate the end of each line with the beginning of the next. (Pick a line out of the middle and notice how much harder it is to recall the *previous* line.)

To simplify, we will explore these two types of associative learning separately. Often, though, they occur together, as on one Japanese cattle

ranch, where the clever rancher outfitted his herd with electronic pagers which he called from his cell phone. After a week of training, the animals learned to associate two stimuli—the beep of their pager and the arrival of food (classical conditioning). But they also learned to associate their hustling to the food trough with the pleasure of eating (operant conditioning), which simplified the rancher's work.

Conditioning is not the only form of learning. Through [cognitive learning](#), we acquire mental information that guides our behavior. *Observational learning*, one form of cognitive learning, lets us learn from others' experiences. Chimpanzees, for example, sometimes learn behaviors merely by watching others perform them. If one animal sees another solve a puzzle and gain a food reward, the observer may perform the trick more quickly. So, too, in humans: We look and we learn.

cognitive learning the acquisition of mental information, whether by observing events, by watching others, or through language.

Let's look more closely now at classical conditioning.

RETRIEVAL PRACTICE

RP-1 Why are habits, such as having something sweet with that cup of coffee, so hard to break?

ANSWER: Habits form when we repeat behaviors in a given context and, as a result, learn associations—often without our awareness. For example, we may have eaten a sweet pastry with a cup of coffee often enough to associate the flavor of the coffee with the treat, so that the cup of coffee alone just doesn't seem right anymore!

Classical Conditioning

LOQ 7-2 What was behaviorism's view of learning?

For many people, the name Ivan Pavlov (1849–1936) rings a bell. His early twentieth-century experiments—now psychology’s most famous research—are classics, and the phenomenon he explored we justly call [classical conditioning](#).

classical conditioning a type of learning in which we link two or more stimuli; as a result, to illustrate with Pavlov’s classic experiment, the first stimulus (a tone) comes to elicit behavior (drooling) in anticipation of the second stimulus (food).

Pavlov’s work laid the foundation for many of psychologist John B. Watson’s ideas. In searching for laws underlying learning, Watson (1913) urged his colleagues to discard reference to inner thoughts, feelings, and motives. The science of psychology should instead study how organisms respond to stimuli in their environments, said Watson: “Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods.” Simply said, psychology should be an objective science based on observable behavior.

This view, which Watson called [behaviorism](#), influenced North American psychology during the first half of the twentieth century. Pavlov and Watson shared both a disdain for “mentalist” concepts (such as consciousness) and a belief that the basic laws of learning were the same for all animals—whether sea slugs or dogs or humans. Few researchers today agree that psychology should ignore mental processes, but most do agree that classical conditioning is a basic form of learning by which all organisms adapt to their environment.

behaviorism the view that psychology (1) should be an objective science that (2) studies behavior without reference to mental processes. Most research psychologists today agree with (1) but not with (2).

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Ivan Pavlov

“Experimental investigation ... should lay a solid foundation for a future true science of psychology” (1927).

Pavlov's Experiments

LOQ 7.3 Who was Pavlov, and what are the basic components of classical conditioning?

Pavlov was driven by a lifelong passion for research. After setting aside his initial plan to follow his father into the Russian Orthodox priesthood, Pavlov earned a medical degree at age 33 and spent the next two decades studying the digestive system. This work earned him Russia's first Nobel Prize. But it was his novel experiments on learning, which consumed the last three decades of his life, that earned this feisty, intense scientist his place in history (Todes, 2014).

Pavlov's new direction came when his creative mind seized on an incidental observation. Without fail, putting food in a dog's mouth caused the animal to salivate. Moreover, the dog began salivating not only to the taste of the food, but also to the mere sight of the food, or the food dish, or the person

delivering the food, or even at the sound of that person's approaching footsteps. At first, Pavlov considered these "psychic secretions" an annoyance—until he realized they pointed to a simple but fundamental form of learning.

Pavlov and his assistants tried to imagine what the dog was thinking and feeling as it drooled in anticipation of the food. This only led them into fruitless debates. So, to explore the phenomenon more objectively, they experimented. To eliminate other possible influences, they isolated the dog in a small room, secured it in a harness, and attached a device to divert its saliva to a measuring instrument ([FIGURE 7.3](#)). From the next room, they presented food—first by sliding in a food bowl, later by blowing meat powder into the dog's mouth at a precise moment. They then paired various [neutral stimuli \(NS\)](#)—events the dog could see or hear but didn't associate with food—with food in the dog's mouth. If a sight or sound regularly signaled the arrival of food, would the dog learn the link? If so, would it begin salivating in anticipation of the food?

FIGURE 7.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.3 Pavlov's device for recording salivation

A tube in the dog's cheek collects saliva, which is measured in a cylinder outside the chamber.

neutral stimulus (NS) In classical conditioning, a stimulus that elicits no response before conditioning.

The answers proved to be Yes and Yes. Just before placing food in the

dog's mouth to produce salivation, Pavlov sounded a tone. After several pairings of tone and food, the dog, now anticipating the meat powder, began salivating to the tone alone. In later experiments, a buzzer,¹ a light, a touch on the leg, even the sight of a circle set off the drooling. (This procedure works with people, too. When hungry young Londoners viewed abstract figures before smelling peanut butter or vanilla, their brain soon responded in anticipation to the abstract images alone [Gottfried et al., 2003].)

A dog does not learn to salivate in response to food in its mouth. Rather, food in the mouth automatically, *unconditionally*, triggers a dog's salivary reflex (**FIGURE 7.4**). Thus, Pavlov called this drooling an **unconditioned response (UR)**. And he called the food an **unconditioned stimulus (US)**.

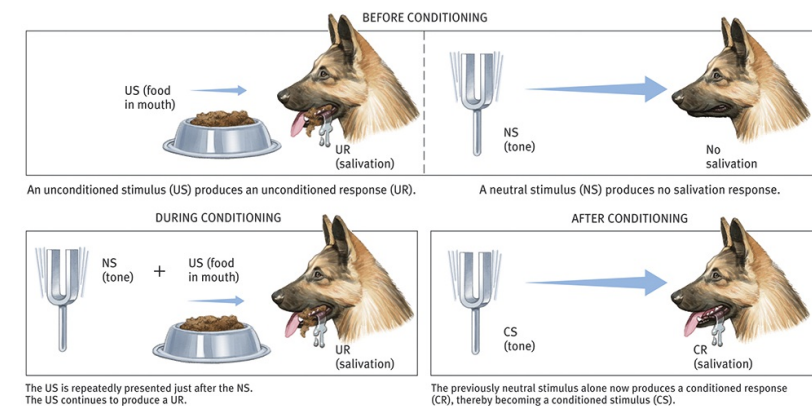

FIGURE 7.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.4 Pavlov's classic experiment

Pavlov presented a neutral stimulus (a tone) just before an unconditioned stimulus (food in mouth). The neutral stimulus then became a conditioned stimulus, producing a conditioned response.

unconditioned response (UR) in classical conditioning, an unlearned, naturally occurring response (such as salivation) to an unconditioned stimulus (US) (such as food in the mouth).

unconditioned stimulus (US) in classical conditioning, a stimulus that unconditionally—naturally and automatically—triggers an unconditioned response (UR).

Salivation in response to a tone, however, is learned. It is *conditional* upon

the dog's associating the tone with the food. Thus, we call this response the **conditioned response (CR)**. The stimulus that used to be neutral (in this case, a previously meaningless tone that now triggers salivation) is the **conditioned stimulus (CS)**. Distinguishing these two kinds of stimuli and responses is easy: Conditioned = learned; *unconditioned* = *unlearned*.

conditioned response (CR) in classical conditioning, a learned response to a previously neutral (but now conditioned) stimulus (CS).

conditioned stimulus (CS) in classical conditioning, an originally neutral stimulus that, after association with an unconditioned stimulus (US), comes to trigger a conditioned response (CR).

If Pavlov's demonstration of associative learning was so simple, what did he do for the next three decades? What discoveries did his research factory publish in his 532 papers on salivary conditioning (Windholz, 1997)? He and his associates explored five major conditioning processes: *acquisition*, *extinction*, *spontaneous recovery*, *generalization*, and *discrimination*.

RETRIEVAL PRACTICE

RP-2 An experimenter sounds a tone just before delivering an air puff that causes your eye to blink. After several repetitions, you blink to the tone alone. What is the NS? The US? The UR? The CS? The CR?

ANSWER: NS = tone before conditioning; US = air puff; UR = blink to air puff; CS = tone after conditioning; CR = blink to tone

ACQUISITION

LOQ 7-4 In classical conditioning, what are the processes of *acquisition*, *extinction*, *spontaneous recovery*, *generalization*, and *discrimination*?

To understand the **acquisition**, or initial learning, of the stimulus-response relationship, Pavlov and his associates wondered: How much time should elapse between presenting the NS (the tone, the light, the touch) and the US (the food)? In most cases, not much—half a second usually works well.

acquisition in classical conditioning, the initial stage, when one links a neutral stimulus and an unconditioned stimulus so that the neutral stimulus begins triggering the conditioned response. In operant conditioning, the strengthening of a reinforced response.

What do you suppose would happen if the food (US) appeared before the tone (NS) rather than after? Would conditioning occur? Not likely. Conditioning usually won't occur when the NS follows the US. *Remember, classical conditioning is biologically adaptive because it helps humans and other animals prepare for good or bad events.* To Pavlov's dogs, the originally neutral tone became a CS after signaling an important biological event—the arrival of food (US). To deer in the forest, the snapping of a twig (CS) may signal a predator's approach (US).

Research on male Japanese quail shows how a CS can signal another important biological event (Domjan, 1992, 1994, 2005). Just before presenting a sexually approachable female quail, the researchers turned on a red light. Over time, as the red light continued to herald the female's arrival, the light alone caused the male quail to become excited. They developed a preference for their cage's red-light district, and when a female appeared, they mated with her more quickly and released more semen and sperm (Matthews et al., 2007). This capacity for classical conditioning gives the quail a reproductive edge.

Sexual conditioning also occurs in rats. When their early sexual

experiences are with partners scented with a peculiar odor, rats later display a preference for similarly scented partners (Pfaus et al., 2012). In humans, too, objects, smells, and sights associated with sexual pleasure—even a geometric figure, in one experiment—can become conditioned stimuli for sexual arousal (Byrne, 1982; Hoffman, 2012). Onion breath does not usually produce sexual arousal. But when repeatedly paired with a passionate kiss, it can become a CS and do just that (**FIGURE 7.5**). The larger lesson: *Conditioning helps an animal survive and reproduce—by responding to cues that help it gain food, avoid dangers, locate mates, and produce offspring* (Hollis, 1997). Learning makes for yearning.

Through **higher-order conditioning**, a new NS can become a new CS without the presence of a US. All that's required is for it to become associated with a previously conditioned stimulus. If a tone regularly signals food and produces salivation, then a light that becomes associated with the tone (light → tone → food) may also begin to trigger salivation. Although this higher-order conditioning (also called *second-order conditioning*) tends to be weaker than first-order conditioning, it influences our everyday lives. Imagine that something makes us very afraid (perhaps a guard dog associated with a previous dog bite). If something else, such as the sound of a barking dog, brings that guard dog to mind, the bark alone may make us feel a little afraid.

higher-order conditioning a procedure in which the conditioned stimulus in one conditioning experience is paired with a new neutral stimulus, creating a second (often weaker) conditioned stimulus. For example, an animal that has learned that a tone predicts food might then learn that a light predicts the tone and begin responding to the light alone. (Also called second-order conditioning.)

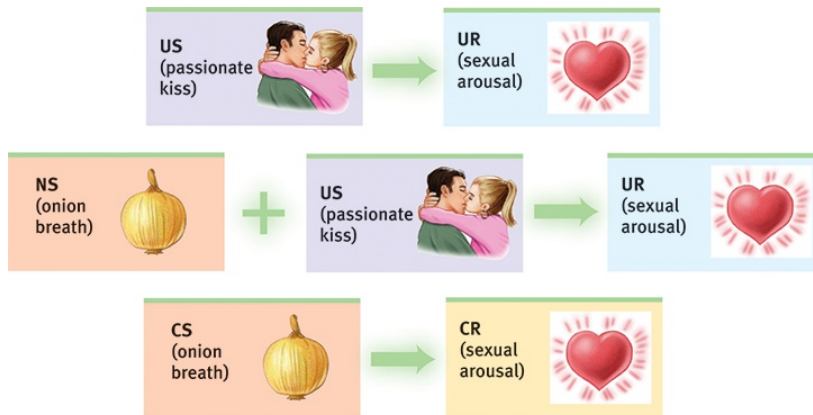

FIGURE 7.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.5 An unexpected CS

Psychologist Michael Tirrell (1990) recalled: “My first girlfriend loved onions, so I came to associate onion breath with kissing. Before long, onion breath sent tingles up and down my spine. Oh what a feeling!”

Remember:

NS = Neutral Stimulus

US = Unconditioned Stimulus

UR = Unconditioned Response

CS = Conditioned Stimulus

CR = Conditioned Response

EXTINCTION AND SPONTANEOUS RECOVERY

What would happen, Pavlov wondered, if, after conditioning, the CS occurred repeatedly without the US? If the tone sounded again and again, but no food appeared, would the tone still trigger salivation? The answer was mixed. The dogs salivated less and less, a reaction known as [extinction](#). Extinction is the diminished response that occurs when the CS (tone) no longer signals an impending US (food). But a different picture emerged when Pavlov allowed several hours to elapse before sounding the tone again. After the delay, the dogs would again begin salivating to the tone ([FIGURE 7.6](#)). This [spontaneous recovery](#)—the reappearance of a (weakened) CR after a pause—suggested to Pavlov that extinction was suppressing the CR rather than eliminating it.

extinction the diminishing of a conditioned response; occurs in classical conditioning when an unconditioned stimulus (US) does not follow a conditioned stimulus (CS); occurs in operant conditioning when a response is no longer reinforced.

spontaneous recovery the reappearance, after a pause, of an extinguished conditioned response.

FIGURE 7.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.6 Idealized curve of acquisition, extinction, and spontaneous recovery

The rising curve shows the CR rapidly growing stronger as the NS becomes a CS due to repeated pairing with the US (*acquisition*). The CR then weakens rapidly as the CS is presented alone (*extinction*). After a pause, the (weakened) CR reappears (*spontaneous recovery*).

RETRIEVAL PRACTICE

RP-3 If the aroma of a baking cake sets your mouth to watering, what is the US? The CS? The CR?

ANSWER: The cake (including its taste) is the US. The associated aroma is the CS. Salivation to the aroma is the CR.

RP-4 The first step of classical conditioning, when an NS becomes a CS, is called _____. When a US no longer follows the CS, and the CR becomes weakened, this is called _____.

ANSWER: acquisition, extinction

GENERALIZATION Pavlov and his students noticed that a dog conditioned to the sound of one tone also responded somewhat to the sound of a new and different tone. Likewise, a dog conditioned to salivate when rubbed would also drool a bit when scratched (Windholz, 1989) or when touched on a different body part (**FIGURE 7.7**). This tendency to respond to stimuli similar to the CS is called **generalization** (or *stimulus generalization*).

FIGURE 7.7 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Data from Pavlov, 1927

FIGURE 7.7 Generalization

Pavlov demonstrated generalization by attaching miniature vibrators to various parts of a dog's body. After conditioning salivation to stimulation of the thigh, he stimulated other areas. The closer a stimulated spot was to the dog's thigh, the stronger the conditioned response.

generalization the tendency, once a response has been conditioned, for stimuli similar to the conditioned stimulus to elicit similar responses. (In operant conditioning, generalization occurs when responses learned in one situation occur in other, similar situations.)

Generalization can be adaptive, as when toddlers who learn to fear moving cars also become afraid of moving trucks and motorcycles. And generalized fears can linger. Years after being tortured, one Argentine writer reported still flinching with fear at the sight of black shoes—his first glimpse of his torturers as they approached his cell. Generalized anxiety reactions have been demonstrated in laboratory studies comparing abused with nonabused children ([FIGURE 7.8](#)). When an angry face appears on a computer screen, abused children's brain-wave responses are dramatically stronger and longer lasting (Pollak et al., 1998). And when a face that we've been conditioned to like (or dislike) is morphed into another face, we also have some tendency to like (or dislike) the vaguely similar morphed face (Gawronski & Quinn, 2013).

FIGURE 7.8 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
© UW-Madison News & Public Affairs, Photo by Jeff Miller

FIGURE 7.8 Child abuse leaves tracks in the brain

Abused children's sensitized brains react more strongly to angry faces (Pollak et al., 1998). This generalized anxiety response may help explain their greater risk of psychological disorder.

Stimuli similar to naturally disgusting objects will, by association, also evoke some disgust. Shape otherwise desirable fudge to resemble dog feces, and people will be repulsed (Rozin et al., 1986). Ditto when sewage gets recycled as pure drinking water (Rozin et al., 2015). Toilet → tap → yuck. In each of these human examples, people's emotional reactions to one stimulus have generalized to similar stimuli.

DISCRIMINATION Pavlov's dogs also learned to respond to the sound of a particular tone and *not* to other tones. This learned ability to *distinguish*

between a conditioned stimulus (which predicts the US) and other, irrelevant stimuli is called **discrimination**. Being able to recognize differences is adaptive. Slightly different stimuli can be followed by vastly different consequences. Facing a guard dog, your heart may race; facing a guide dog, it probably will not.

discrimination in classical conditioning, the learned ability to distinguish between a conditioned stimulus and similar stimuli that do not signal an unconditioned stimulus. (In operant conditioning, the ability to distinguish responses that are reinforced from similar responses that are not reinforced.)

RETRIEVAL PRACTICE

RP-5 What conditioning principle is influencing the snail's affections?

ANSWER: generalization

Pavlov's Legacy

LOQ 7-5 Why does Pavlov's work remain so important?

What remains today of Pavlov's ideas? A great deal. Most psychologists now

agree that classical conditioning is a basic form of learning. Judged with today's knowledge of the interplay of our biology, psychology, and social-cultural environment, Pavlov's ideas were incomplete. But if we see further than Pavlov did, it is because we stand on his shoulders.

Why does Pavlov's work remain so important? If he had merely taught us that old dogs can learn new tricks, his experiments would long ago have been forgotten. Why should we care that dogs can be conditioned to salivate to the sound of a tone? The importance lies, first, in the finding that *many other responses to many other stimuli can be classically conditioned in many other organisms*—in fact, in every species tested, from earthworms to fish to dogs to monkeys to people (Schwartz, 1984). Thus, classical conditioning is one way that virtually all organisms learn to adapt to their environment.

Second, *Pavlov showed us how a process such as learning can be studied objectively*. He was proud that his methods involved virtually no subjective judgments or guesses about what went on in a dog's mind. The salivary response is a behavior measurable in cubic centimeters of saliva. Pavlov's success therefore suggested a scientific model for how the young discipline of psychology might proceed—by isolating the basic building blocks of complex behaviors and studying them with objective laboratory procedures.

RETRIEVAL PRACTICE

RP-6 In slasher movies, sexually arousing images of women are sometimes paired with violence against women. Based on classical conditioning principles, what might be an effect of this pairing?

ANSWER: If viewing an attractive nude or seminude woman (a US) elicits sexual arousal (a UR), then pairing the US with a new NS (violence) could turn the violence into a conditioned stimulus (CS) that also becomes sexually arousing, a conditioned response (CR).

To review Pavlov's classic work and to play the role of experimenter in classical conditioning research, visit PsychSim 6: Classical Conditioning. See also a 3-minute re-creation of Pavlov's lab in the Video: Pavlov's Discovery of Classical Conditioning.

APPLICATIONS OF CLASSICAL CONDITIONING

LOQ 7-6 What have been some applications of Pavlov's work to human health and well-being? How did Watson apply Pavlov's principles to learned fears?

Other chapters in this text—on consciousness, motivation, emotion, health, psychological disorders, and therapy—show how Pavlov's principles can influence human health and well-being. Three examples:

- *Drug cravings.* Former drug users often feel a craving when they are again in the drug-using context—with people or in places they associate with previous highs. Thus, drug counselors advise their clients to steer clear of people and settings that may trigger these cravings (Siegel, 2005).
- *Food cravings.* Classical conditioning makes dieting difficult. We readily associate sugary substances with an enjoyable sweet sensation. Researchers have conditioned healthy volunteers to experience cravings after only one instance of eating a sweet food (Blechert et al., 2016). Eating one cookie can create hunger for another. People who struggle with their weight often have eaten unhealthy foods thousands of times, leaving them with strongly conditioned responses to eat the very foods that will keep them in poor health (Hill, 2007).
- *Immune responses.* Classical conditioning even works on the body's disease-fighting immune system. When a particular taste accompanies a drug that influences immune responses, the taste by itself may come to produce an immune response (Ader & Cohen, 1985).

Pavlov's work also provided a basis for Watson's (1913) idea that human emotions and behaviors, though biologically influenced, are mainly a bundle of conditioned responses. Working with an 11-month-old, Watson and his graduate student Rosalie Rayner (1920; Harris, 1979) showed how specific fears might be conditioned. Like most infants, "Little Albert" feared loud noises but not white rats. Watson and Rayner presented a white rat and, as Little Albert reached to touch it, struck a hammer against a steel bar just behind his head. After seven repeats of seeing the rat and hearing the frightening noise, Albert burst into tears at the mere sight of the rat. Five days later, he had generalized this startled fear reaction to the sight of a rabbit, a dog, and a sealskin coat, but not to dissimilar objects, such as toys.

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

John B. Watson

Watson (1924) admitted to “going beyond my facts” when offering his famous boast: “Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I’ll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchant-chief, and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors.”

For years, people wondered what became of Little Albert. Sleuthing by Russell Powell and his colleagues (2014) found a well-matched child of one of the hospital’s wet nurses. The child, William Albert Barger, went by Albert B.—precisely the name used by Watson and Rayner. This Albert, who died in 2007, was an easygoing person, though, perhaps coincidentally, he had an aversion to dogs. He died without ever knowing of his early life in a hospital residence or his role in psychology’s history.

People also wondered what became of Watson. After losing his Johns Hopkins professorship over an affair with Rayner (whom he later married), he joined an advertising agency as the company’s resident psychologist. There, he used his knowledge of associative learning to conceive many

successful advertising campaigns, including one for Maxwell House that helped make the “coffee break” an American custom (Hunt, 1993).

The treatment of Little Albert would be unethical by today’s standards. Also, some psychologists had difficulty repeating Watson and Rayner’s findings with other children. Nevertheless, Little Albert’s learned fears led many psychologists to wonder whether each of us might be a walking warehouse of conditioned emotions. If so, might extinction procedures or new conditioning help us change our unwanted responses to emotion-arousing stimuli?

See the Video: Research Ethics for a helpful tutorial animation.

One patient, who for 30 years had feared entering an elevator alone, did just that. Following his therapist’s advice, he forced himself to enter 20 elevators a day. Within 10 days, his fear had nearly vanished (Ellis & Becker, 1982). With support from airline AirTran, comedian-writer Mark Malkoff likewise extinguished his fear of flying. He lived on an airplane for 30 days, taking 135 flights that had him in the air 14 hours a day (NPR, 2009). After a week and a half, his fears had faded and he began playing games with fellow passengers. (His favorite antic was the “toilet paper experiment”: He’d put one end of a roll in the toilet, unroll the rest down the aisle, and flush. The entire roll would be sucked down in three seconds.) In [Chapter 16](#) we will see more examples of how psychologists use behavioral techniques such as *counterconditioning* to treat emotional disorders and promote personal growth.

RETRIEVAL PRACTICE

RP-7 In Watson and Rayner’s experiments, “Little Albert” learned to fear a white rat after repeatedly experiencing a loud noise as the rat was presented. In these experiments, what was the US? The UR? The NS? The CS? The CR?

Archives of the History of American Psychology, The Center for the History of Psychology, The University of Akron

ANSWER: The US was the loud noise; the UR was the fear response to the noise; the NS was the rat before it was paired with the noise; the CS was the rat after pairing; the CR was fear of the rat.

REVIEW Basic Learning Concepts and Classical Conditioning

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Learning is defined as “the process of acquiring through experience new and relatively enduring _____ or _____.”

Two forms of associative learning are classical conditioning, in which the organism associates _____, and operant conditioning, in which the organism associates _____.

- a. two or more responses; a response and consequence
- b. two or more stimuli; two or more responses
- c. two or more stimuli; a response and consequence
- d. two or more responses; two or more stimuli

In Pavlov’s experiments, the tone started as a neutral stimulus, and then became a(n) _____ stimulus.

Dogs have been taught to salivate to a circle but not to a square.

This process is an example of _____.

After Watson and Rayner classically conditioned Little Albert to fear a white rat, the child later showed fear in response to a rabbit, a dog, and a sealskin coat. This illustrates

- a. extinction.
- b. generalization.
- c. spontaneous recovery.
- d. discrimination between two stimuli.

“Sex sells!” is a common saying in advertising. Using classical conditioning terms, explain how sexual images in advertisements can condition your response to a product.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Operant Conditioning

LOQ 7-7 What is *operant conditioning*?

It's one thing to classically condition a dog to salivate to the sound of a tone, or a child to fear moving cars. But to teach an elephant to walk on its hind legs or a child to say *please*, we turn to operant conditioning.

Classical conditioning and operant conditioning are both forms of associative learning, yet their differences are straightforward:

- *Classical conditioning* forms associations between stimuli (a CS and the US it signals). It also involves *respondent behavior*—automatic responses to a stimulus (such as salivating in response to meat powder and later in response to a tone).
- In **operant conditioning**, organisms associate their own actions with consequences. Actions followed by reinforcers increase; those followed by punishments often decrease. Behavior that *operates* on the environment to produce rewarding or punishing stimuli is called *operant behavior*.

operant conditioning a type of learning in which a behavior becomes more likely to recur if followed by a reinforcer or less likely to recur if followed by a punisher.

RETRIEVAL PRACTICE

RP-8 With classical conditioning, we learn associations between events we _____ (do/do not) control. With operant conditioning, we learn associations between our behavior and _____ (resulting/random) events.

ANSWER: do not; resulting

Skinner's Experiments

LOQ 7-8 Who was Skinner, and how is operant behavior reinforced and shaped?

B. F. Skinner (1904–1990) was a college English major and aspiring writer who, seeking a new direction, enrolled as a graduate student in psychology. He went on to become modern behaviorism's most influential and controversial figure. Skinner's work elaborated on what psychologist Edward L. Thorndike (1874–1949) called the **law of effect**: Rewarded behavior tends to recur (**FIGURE 7.9**), and punished behavior is less likely to recur. Using Thorndike's law of effect as a starting point, Skinner developed a behavioral technology that revealed principles of *behavior control*. By shaping pigeons' natural walking and pecking behaviors, for example, Skinner was able to teach them such unpigeon-like behaviors as walking in a figure 8, playing Ping-Pong, and keeping a missile on course by pecking at a screen target.

law of effect Thorndike's principle that behaviors followed by favorable consequences become more likely, and that behaviors followed by unfavorable consequences become less likely.

FIGURE 7.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Thorndike, 1898.

FIGURE 7.9 Cat in a puzzle box

Thorndike used a fish reward to entice cats to find their way out of a puzzle box through a series of maneuvers. The cats' performance tended to improve with successive trials, illustrating Thorndike's *law of effect*.

For his pioneering studies, Skinner designed an **operant chamber**, popularly known as a *Skinner box* (**FIGURE 7.10**). The box has a bar (a lever) that an animal presses—or a key (a disc) the animal pecks—to release a reward of food or water. It also has a device that records these responses.

This creates a stage on which rats and other animals act out Skinner's concept of **reinforcement**: any event that strengthens (increases the frequency of) a preceding response. What is reinforcing depends on the animal and the conditions. For people, it may be praise, attention, or a paycheck. For hungry and thirsty rats, food and water work well. Skinner's experiments have done far more than teach us how to pull habits out of a rat. They have explored the precise conditions that foster efficient and enduring learning.

operant chamber in operant conditioning research, a chamber (also known as a *Skinner box*) containing a bar or key that an animal can manipulate to obtain a food or water reinforcer; attached devices record the animal's rate of bar pressing or key pecking.

reinforcement in operant conditioning, any event that *strengthens* the behavior it follows.

FIGURE 7.10 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 7.10 A Skinner box

Inside the box, the rat presses a bar for a food reward. Outside, measuring devices (not shown here) record the animal's accumulated responses.

Shaping Behavior

Imagine that you wanted to condition a hungry rat to press a bar. Like Skinner, you could tease out this action with **shaping**, gradually guiding the rat's actions toward the desired behavior. First, you would watch how the

animal naturally behaves, so that you could build on its existing behaviors. You might give the rat a bit of food each time it approaches the bar. Once the rat is approaching regularly, you would give the food only when it moves close to the bar, then closer still. Finally, you would require it to touch the bar to get food. By rewarding *successive approximations*, you reinforce responses that are ever closer to the final desired behavior, and you ignore all other responses. By making rewards contingent on desired behaviors, researchers and animal trainers gradually shape complex behaviors.

shaping an operant conditioning procedure in which reinforcers guide behavior toward closer and closer approximations of the desired behavior.

Shaping can also help us understand what nonverbal organisms perceive. Can a dog distinguish red and green? Can a baby hear the difference between lower- and higher-pitched tones? If we can shape them to respond to one stimulus and not to another, then we know they can perceive the difference. Such experiments have even shown that some nonhuman animals can form concepts. When experimenters reinforced pigeons for pecking after seeing a human face, but not after seeing other images, the pigeon's behavior showed that it could recognize human faces (Herrnstein & Loveland, 1964). In this experiment, the human face was a *discriminative stimulus*. Like a green traffic light, discriminative stimuli signal that a response will be reinforced. After being trained to discriminate among classes of events or objects—flowers, people, cars, chairs—pigeons can usually identify the category in which a new pictured object belongs (Bhatt et al., 1988; Wasserman, 1993). They have even been trained to discriminate between the music of Bach and Stravinsky (Porter & Neuringer, 1984).

Will Burgess/Reuters/Newscom

Reinforcers vary with circumstances

What is reinforcing (a heat lamp) to one animal (a cold meerkat) may not be to another (an overheated child). What is reinforcing in one situation (a cold snap at the Taronga Zoo in Sydney) may not be in another (a sweltering summer day).

Skinner noted that we continually reinforce and shape others' everyday behaviors, though we may not mean to do so. Isaac's whining annoys his dad, for example, but consider how his dad typically responds:

ISAAC: Could you take me to the mall?

DAD: (Continues reading paper.)

ISAAC: Dad, I need to go to the mall.

DAD: Uh, yeah, in a few minutes.

ISAAC: DAAAAD! The mall!!

DAD: Show me some manners! Okay, where are my keys . . .

Isaac's whining is reinforced, because he gets something desirable—a trip to the mall. Dad's response is reinforced, because it gets rid of something aversive—Isaac's whining.

Or consider a teacher who sticks gold stars on a wall chart beside the

names of children scoring 100 percent on spelling tests. As everyone can then see, some children consistently do perfect work. The others, who may have worked harder than the academic all-stars, get no rewards. The teacher would be better advised to apply the principles of operant conditioning—to reinforce all spellers for gradual improvements (successive approximations toward perfect spelling of words they find challenging).

Levenson RM, Krupinski EA, Navarro VM, Wasserman EA (2015). Pigeons (*Columba livia*) as Trainable Observers of Pathology and Radiology Breast Cancer Images. PLoS ONE 10(11): e0141357.

Bird brains spot tumors

After being rewarded with food when correctly spotting breast tumors, pigeons became as skilled as humans at discriminating cancerous from healthy tissue (Levenson et al., 2015). Other animals have been shaped to sniff out land mines or locate people amid rubble (La Londe et al., 2015).

Types of Reinforcers

LOQ 7-9 How do positive and negative reinforcement differ, and what are the basic types of reinforcers?

Until now, we've mainly been discussing **positive reinforcement**, which strengthens responding by *presenting* a typically *pleasurable* stimulus immediately after a response. But, as the whining Isaac story illustrates, there

are two basic kinds of reinforcement ([TABLE 7.1](#)). **Negative reinforcement** strengthens a response by *reducing or removing* something *negative*. Isaac's whining was *positively* reinforced, because Isaac got something desirable—a trip to the mall. His dad's response (doing what Isaac wanted) was *negatively* reinforced, because it ended an aversive event—Isaac's whining. Similarly, taking aspirin may relieve your headache, and hitting *snooze* will silence your irritating alarm. These welcome results provide negative reinforcement and increase the odds that you will repeat these behaviors. For those with drug addiction, the negative reinforcement of ending withdrawal pangs can be a compelling reason to resume using (Baker et al., 2004). Note that *negative reinforcement is not punishment*. (Some friendly advice: Repeat those italicized words in your mind.) Rather, negative reinforcement—psychology's most misunderstood concept—*removes* a punishing (aversive) event. Think of negative reinforcement as something that provides relief—from that whining child, a bad headache, or an annoying alarm.

positive reinforcement increasing behaviors by presenting positive reinforcers. A positive reinforcer is any stimulus that, when *presented* after a response, strengthens the response.

negative reinforcement increasing behaviors by stopping or reducing negative stimuli. A negative reinforcer is any stimulus that, when *removed* after a response, strengthens the response. (Note: Negative reinforcement is not punishment.)

TABLE 7.1
Ways to Increase Behavior

Operant Conditioning Term	Description	Examples
<i>Positive reinforcement</i>	Add a desirable stimulus	Pet a dog that comes when you call it; pay someone for work done.
<i>Negative</i>	Remove an	Take painkillers to end pain; fasten

reinforcement	aversive stimulus	seatbelt to end loud beeping.

RETRIEVAL PRACTICE

RP-9 How is operant conditioning at work in this cartoon?

Hi & Lois © 1992 by King Features Syndicate, Inc. World rights reserved.

ANSWER: The baby negatively reinforces her parents' behavior when she stops crying once they grant her wish. Her parents positively reinforce her cries by letting her sleep with them.

Sometimes negative and positive reinforcement coincide. Imagine a worried student who, after goofing off and getting a bad exam grade, studies harder for the next exam. This increased effort may be *negatively* reinforced by reduced anxiety, and *positively* reinforced by a better grade. We reap the rewards of escaping the aversive stimulus, which increases the chances that we will repeat our behavior. *The point to remember:* Whether it works by reducing something aversive, or by providing something desirable, *reinforcement is any consequence that strengthens behavior.*

PRIMARY AND CONDITIONED REINFORCERS Getting food when hungry or having a painful headache go away is innately satisfying. These **primary reinforcers** are unlearned. **Conditioned reinforcers**, also called *secondary reinforcers*, get their power through learned association with primary reinforcers. If a rat in a Skinner box learns that a light reliably signals a food delivery, the rat will work to turn on the light (see [Figure 7.10](#)). The light has become a conditioned reinforcer. Our lives are filled with conditioned reinforcers—money, good grades, a pleasant tone of voice—each of which has been linked with more basic rewards. If money is a conditioned reinforcer—if people's desire for money is derived from their desire for food

—then hunger should also make people more money hungry, reasoned one European research team (Briers et al., 2006). Indeed, in their experiments, people were less likely to donate to charity when food deprived, and less likely to share money with fellow participants when in a room with hunger-arousing aromas.

primary reinforcer an innately reinforcing stimulus, such as one that satisfies a biological need.

conditioned reinforcer a stimulus that gains its reinforcing power through its association with a primary reinforcer; also known as a *secondary reinforcer*.

IMMEDIATE AND DELAYED REINFORCERS Let's return to the imaginary shaping experiment in which you were conditioning a rat to press a bar. Before performing this “wanted” behavior, the hungry rat will engage in a sequence of “unwanted” behaviors—scratching, sniffing, and moving around. If you present food immediately after any one of these behaviors, the rat will likely repeat that rewarded behavior. But what if the rat presses the bar while you are distracted, and you delay giving the reinforcer? If the delay lasts longer than about 30 seconds, the rat will not learn to press the bar. It will have moved on to other incidental behaviors, such as scratching, sniffing, and moving, and one of these behaviors will instead get reinforced.

Unlike rats, humans do respond to delayed reinforcers: the paycheck at the end of the week, the good grade at the end of the term, the trophy at the end of the sports season. Indeed, to function effectively we must learn to delay gratification. In one of psychology's most famous studies, some 4-year-olds showed this ability. In choosing a piece of candy or a marshmallow, these impulse-controlled children preferred having a big one tomorrow to munching on a small one right away. Learning to control our impulses in order to achieve more valued rewards is a big step toward maturity and can later protect us from committing an impulsive crime (Åkerlund et al., 2016; Logue, 1998a,b). Children who delay gratification have tended to become socially competent and high-achieving adults (Mischel, 2014).

To our detriment, small but immediate pleasures (the enjoyment of watching late-night TV, for example) are sometimes more alluring than big

but delayed rewards (feeling rested for a big exam tomorrow). For many teens, the immediate gratification of risky, unprotected sex in passionate moments prevails over the delayed gratifications of safe sex or saved sex. And for many people, the immediate rewards of today's gas-guzzling vehicles, air travel, and air conditioning prevail over the bigger future consequences of global climate change, rising seas, and extreme weather.

Reinforcement Schedules

LOQ 7-10 How do different reinforcement schedules affect behavior?

In most of our examples, the desired response has been reinforced every time it occurs. But **reinforcement schedules** vary. With **continuous reinforcement**, learning occurs rapidly, which makes it the best choice for mastering a behavior. But extinction also occurs rapidly. When reinforcement stops—when we stop delivering food after the rat presses the bar—the behavior soon stops (is *extinguished*). If a normally dependable candy machine fails to deliver a chocolate bar twice in a row, we stop putting money into it (although a week later we may exhibit *spontaneous recovery* by trying again).

reinforcement schedule a pattern that defines how often a desired response will be reinforced.

continuous reinforcement schedule reinforcing the desired response every time it occurs.

Real life rarely provides continuous reinforcement. Salespeople do not make a sale with every pitch. But they persist because their efforts are occasionally rewarded. This persistence is typical with **partial (intermittent) reinforcement schedules**, in which responses are sometimes reinforced, sometimes not. Learning is slower to appear, but *resistance to extinction* is greater than with continuous reinforcement. Imagine a pigeon that has learned to peck a key to obtain food. If you gradually phase out the food

delivery until it occurs only rarely, in no predictable pattern, the pigeon may peck 150,000 times without a reward (Skinner, 1953). Slot machines reward gamblers in much the same way—occasionally and unpredictably. And like pigeons, slot players keep trying, time and time again. With intermittent reinforcement, hope springs eternal.

partial (intermittent) reinforcement schedule reinforcing a response only part of the time; results in slower acquisition of a response but much greater resistance to extinction than does continuous reinforcement.

Lesson for parents: Partial reinforcement also works with children. Occasionally giving in to children's tantrums for the sake of peace and quiet intermittently reinforces the tantrums. This is the very best procedure for making a behavior persist.

"Oh, not bad. The light comes on, I press the bar, they write me a check. How about you?"

The New Yorker Collection, 1993, Tom Cheney from cartoonbank.com. All Rights Reserved.

Skinner (1961) and his collaborators compared four schedules of partial reinforcement. Some are rigidly fixed, some unpredictably variable.

Fixed-ratio schedules reinforce behavior after a set number of responses. Coffee shops may reward us with a free drink after every 10 purchased. Once conditioned, rats may be reinforced on a fixed ratio of, say, one food pellet for every 30 responses. Once conditioned, animals will pause only briefly after a reinforcer before returning to a high rate of responding ([FIGURE 7.11](#)).

fixed-ratio schedule in operant conditioning, a reinforcement schedule that reinforces a response only after a specified number of responses.

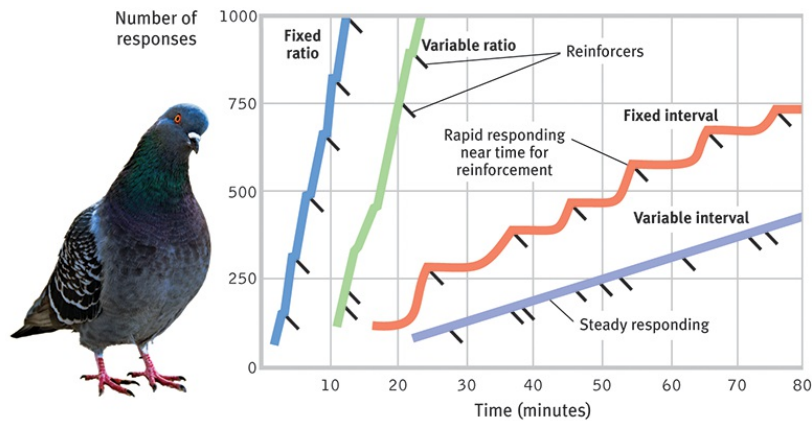

FIGURE 7.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Vitally Titov/Shutterstock; Data from Skinner, 1961.

FIGURE 7.11 Intermittent reinforcement schedules

Skinner's (1961) laboratory pigeons produced these response patterns to each of four reinforcement schedules. (Reinforcers are indicated by diagonal marks.) For people, as for pigeons, reinforcement linked to number of responses (*a ratio schedule*) produces a higher response rate than reinforcement linked to amount of time elapsed (*an interval schedule*). But the predictability of the reward also matters. An unpredictable (*variable*) schedule produces more consistent responding than does a predictable (*fixed*) schedule.

Variable-ratio schedules provide reinforcers after a seemingly unpredictable number of responses. This unpredictable reinforcement is what slot-machine players and fly fishers experience, and it's what makes gambling and fly fishing so hard to extinguish even when they don't produce the desired results. Because reinforcers increase as the number of responses increases, variable-ratio schedules produce high rates of responding.

variable-ratio schedule in operant conditioning, a reinforcement schedule that reinforces a response after an unpredictable number of responses.

“The charm of fishing is that it is the pursuit of what is elusive but

attainable, a perpetual series of occasions for hope.”

Scottish author John Buchan (1875–1940)

Fixed-interval schedules reinforce the first response after a fixed time period. Animals on this type of schedule tend to respond more frequently as the anticipated time for reward draws near. People check more frequently for the mail as the delivery time approaches. A hungry child jiggles the Jell-O more often to see if it has set. Pigeons peck keys more rapidly as the time for reinforcement draws nearer. This produces a choppy stop-start pattern rather than a steady rate of response (see [Figure 7.11](#)).

fixed-interval schedule in operant conditioning, a reinforcement schedule that reinforces a response only after a specified time has elapsed.

Variable-interval schedules reinforce the first response after *varying* time intervals. At unpredictable times, a food pellet rewarded Skinner’s pigeons for persistence in pecking a key. Like the longed-for message that finally rewards persistence in checking our phone, variable-interval schedules tend to produce slow, steady responding. This makes sense, because there is no knowing when the waiting will be over ([TABLE 7.2](#)).

variable-interval schedule in operant conditioning, a reinforcement schedule that reinforces a response at unpredictable time intervals.

TABLE 7.2

Schedules of Partial Reinforcement

	Fixed	Variable
<i>Ratio</i>	<i>Every so many</i> : reinforcement after every <i>n</i> th behavior, such as buy 10 coffees, get 1 free, or pay workers per product	<i>After an unpredictable number</i> : reinforcement after a random number of behaviors, as when playing

	unit produced	slot machines or fly fishing
<i>Interval</i>	<i>Every so often</i> : reinforcement for behavior after a fixed time, such as Tuesday discount prices	<i>Unpredictably often</i> : reinforcement for behavior after a random amount of time, as when checking our phone for a message

In general, response rates are higher when reinforcement is linked to the number of responses (a ratio schedule) rather than to time (an interval schedule). But responding is more consistent when reinforcement is unpredictable (a variable schedule) than when it is predictable (a fixed schedule). Animal behaviors differ, yet Skinner (1956) contended that the reinforcement principles of operant conditioning are universal. It matters little, he said, what response, what reinforcer, or what species you use. The effect of a given reinforcement schedule is pretty much the same: “Pigeon, rat, monkey, which is which? It doesn’t matter . . . Behavior shows astonishingly similar properties.”

RETRIEVAL PRACTICE

RP-10 People who send spam e-mail are reinforced by which schedule? Home bakers checking the oven to see if the cookies are done are on which schedule? Sandwich shops that offer a free sandwich after every 10 sandwiches purchased are using which reinforcement schedule?

ANSWER: Spammers are reinforced on a variable-ratio schedule (after sending a varying number of e-mails). Cookie checkers are reinforced on a fixed-interval schedule. Sandwich shop programs use a fixed-ratio schedule.

Punishment

LOQ 7-11 How does punishment differ from negative reinforcement,

and how does punishment affect behavior?

Reinforcement increases a behavior; **punishment** does the opposite. So, while negative reinforcement *increases* the frequency of a preceding behavior (by withdrawing something negative), a *punisher* is any consequence that *decreases* the frequency of a preceding behavior (**TABLE 7.3**). Swift and sure punishers can powerfully restrain unwanted behavior. The rat that is shocked after touching a forbidden object and the child who is burned by touching a hot stove will learn not to repeat those behaviors.

punishment an event that tends to *decrease* the behavior that it follows.

TABLE 7.3
Ways to Decrease Behavior

Type of Punisher	Description	Examples
<i>Positive punishment</i>	Administer an aversive stimulus.	Spray water on a barking dog; give a traffic ticket for speeding.
<i>Negative punishment</i>	Withdraw a rewarding stimulus.	Take away a misbehaving teen's driving privileges; revoke a rude person's chat room access.

Criminal behavior, much of it impulsive, is also influenced more by swift and sure punishers than by the threat of severe sentences (Darley & Alter, 2013). Thus, when Arizona introduced an exceptionally harsh sentence for first-time drunk drivers, the drunk-driving rate changed very little. But when Kansas City police started patrolling a high crime area to increase the swiftness and sureness of punishment, that city's crime rate dropped dramatically.

What do punishment studies imply for parenting? One analysis of over 160,000 children found that physical punishment rarely corrects unwanted

behavior (Gershoff & Grogan-Kaylor, 2016). Many psychologists note four major drawbacks of physical punishment (Finkenauer et al., 2015; Gershoff, 2002; Marshall, 2002).

1. *Punished behavior is suppressed, not forgotten. This temporary state may (negatively) reinforce parents' punishing behavior.* The child swears, the parent swats, the parent hears no more swearing and feels the punishment successfully stopped the behavior. No wonder spanking is a hit with so many parents—with 60 percent of children around the world spanked or otherwise physically punished (UNICEF, 2014).
2. *Punishment teaches discrimination among situations.* In operant conditioning, *discrimination* occurs when an organism learns that certain responses, but not others, will be reinforced. Did the punishment effectively end the child's swearing? Or did the child simply learn that while it's not okay to swear around the house, it's okay elsewhere?
3. *Punishment can teach fear.* In operant conditioning, *generalization* occurs when an organism's response to similar stimuli is also reinforced. A punished child may associate fear not only with the undesirable behavior but also with the person who delivered the punishment or where it occurred. Thus, children may learn to fear a punishing teacher and try to avoid school, or may become more anxious (Gershoff et al., 2010). For such reasons, most European countries and 31 U.S. states now ban hitting children in schools and child-care institutions (EndCorporalPunishment.org). As of 2017, 51 countries outlaw hitting by parents. A large survey in Finland, the second country to pass such a law, revealed that children born after the law passed were, indeed, less often slapped and beaten (Österman et al., 2014).
4. *Physical punishment may increase aggression by modeling violence as a way to cope with problems.* Studies find that spanked children are at increased risk for aggression (MacKenzie et al., 2013). We know, for example, that many aggressive delinquents and abusive parents come from abusive families (Straus & Gelles, 1980; Straus et al., 1997).

Some researchers question this logic. Physically punished children may be more aggressive, they say, for the same reason that people who have undergone psychotherapy are more likely to suffer depression—because they had preexisting problems that triggered the treatments (Ferguson, 2013a;

Larzelere, 2000; Larzelere et al., 2004). So, does spanking cause misbehavior, or does misbehavior trigger spanking? Correlations don't hand us an answer.

See the **Video: Correlational Studies** for a helpful tutorial animation.

The debate continues. Some researchers note that frequent spankings predict future aggression—even when studies control for preexisting bad behavior (Taylor et al., 2010). Other researchers believe that lighter spankings pose less of a problem (Baumrind et al., 2002; Larzelere & Kuhn, 2005). That is especially so if physical punishment is used only as a backup for milder disciplinary tactics, and if it is combined with a generous dose of reasoning and reinforcing.

Parents of delinquent youths are often unaware of how to achieve desirable behaviors without screaming, hitting, or threatening their children with punishment (Patterson et al., 1982). Training programs can help transform dire threats (“You clean up your room this minute or no dinner!”) into positive incentives (“You’re welcome at the dinner table after you get your room cleaned up”). Stop and think about it. Aren’t many threats of punishment just as forceful, and perhaps more effective, when rephrased positively? Thus, “If you don’t get your homework done, there’ll be no car” could be phrased more positively as

In classrooms, too, teachers can give feedback by saying, “No, but try this . . .” and “Yes, that’s it!” Such responses reduce unwanted behavior while reinforcing more desirable alternatives. Remember: *Punishment tells you what not to do; reinforcement tells you what to do.* Thus, punishment trains a particular sort of morality—one focused on prohibition (what *not* to do) rather than positive obligations (Sheikh & Janoff-Bulman, 2013).

What punishment often teaches, said Skinner, is how to avoid it. Most psychologists now favor an emphasis on reinforcement: Notice people doing something right and affirm them for it.

RETRIEVAL PRACTICE

RP-11 Fill in the three blanks below with one of the following terms: positive reinforcement (PR), negative reinforcement (NR), positive punishment (PP), and negative punishment (NP).

We have provided the first answer (PR) for you.

Type of Stimulus	Give It	Take It Away
Desired (for example, a teen's use of the car)	1. PR	2.
Undesired/aversive (for example, an insult)	3.	4.

ANSWER: 1. PR (positive reinforcement); 2. NP (negative punishment); 3. PP (positive punishment);

“A pat on the back, though only a few vertebrae removed from a kick in the pants, is miles ahead in results.”

Skinner's Legacy

LOQ 7-12 Why did Skinner's ideas provoke controversy, and how might his operant conditioning principles be applied at school, in sports, at work, in parenting, and for self-improvement?

B. F. Skinner stirred a hornet's nest with his outspoken beliefs. He repeatedly insisted that external influences, not internal thoughts and feelings, shape behavior. He argued that brain science isn't needed for psychological science, saying that “a science of behavior is independent of neurology” (Skinner, 1938/1966, pp. 423–424). And he urged people to use operant conditioning principles to influence others' behavior at school, work, and home. Knowing that behavior is shaped by its results, he argued that we should use rewards to evoke more desirable behavior.

Skinner's critics objected, saying that he dehumanized people by neglecting their personal freedom and by seeking to control their actions.

Skinner's reply: External consequences already haphazardly control people's behavior. Why not administer those consequences toward human betterment? Wouldn't reinforcers be more humane than the punishments used in homes, schools, and prisons? And if it is humbling to think that our history has shaped us, doesn't this very idea also give us hope that we can shape our future?

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

B. F. Skinner

"I am sometimes asked, 'Do you think of yourself as you think of the organisms you study?' The answer is yes. So far as I know, my behavior at any given moment has been nothing more than the product of my genetic endowment, my personal history, and the current setting" (1983).

Applications of Operant Conditioning

In later chapters, we will see how psychologists apply operant conditioning principles to help people moderate high blood pressure or gain social skills. Reinforcement techniques are also at work in schools, sports, workplaces, and homes, and these principles can support our self-improvement as well (Flora, 2004).

AT SCHOOL More than 50 years ago, Skinner and others worked toward a day when “machines and textbooks” would shape learning in small steps, by immediately reinforcing correct responses. Such machines and textbooks, they said, would revolutionize education and free teachers to focus on each student’s special needs. “Good instruction demands two things,” said Skinner (1989). “Students must be told immediately whether what they do is right or wrong and, when right, they must be directed to the step to be taken next.”

Operant conditioning principles may be used to help us reach our goals. What else affects our goal achievement? To find out, engage online with Assess Your Strengths: How Might Your Willingness to Think of the Future Affect Your Ability to Achieve Long-Term Goals?

Skinner might be pleased to know that many of his ideals for education are now possible. Teachers used to find it difficult to pace material to each student’s rate of learning, and to provide prompt feedback. Online adaptive quizzing, such as the LearningCurve system available with this text, does both. Students move through quizzes at their own pace, according to their own level of understanding. And they get immediate feedback on their efforts, including personalized study plans.

IN SPORTS The key to shaping behavior in athletic performance, as elsewhere, is first reinforcing small successes and then gradually increasing the challenge. Golf students can learn putting by starting with very short putts, and then, as they build mastery, stepping back farther and farther. Novice batters can begin with half swings at an oversized ball pitched from 10 feet away, giving them the immediate pleasure of smacking the ball. As the hitters’ confidence builds with their success and they achieve mastery at each level, the pitcher gradually moves back and eventually introduces a standard baseball. Compared with children taught by conventional methods, those trained by this behavioral method have shown faster skill improvement (Simek & O’Brien, 1981, 1988).

AT WORK Knowing that reinforcers influence productivity, many organizations have invited employees to share the risks and rewards of company ownership. Others focus on reinforcing a job well done. Rewards are most likely to increase productivity if the desired performance is both well defined and achievable. The message for managers? *Reward specific, achievable behaviors, not vaguely defined “merit.”*

Operant conditioning also reminds us that reinforcement should be *immediate*. IBM legend Thomas Watson understood this. When he observed an achievement, he wrote the employee a check on the spot (Peters & Waterman, 1982). But rewards need not be material, or lavish. An effective manager may simply walk the floor and sincerely affirm people for good work, or write notes of appreciation for a completed project. As Skinner said, “How much richer would the whole world be if the reinforcers in daily life were more effectively contingent on productive work?”

The New Yorker Collection, 1989, Ziegler from cartoonbank.com. All Rights Reserved.

IN PARENTING As we have seen, parents can learn from operant conditioning practices. Parent-training researchers remind us that by saying, “Get ready for bed” and then caving in to protests or defiance, parents reinforce such whining and arguing (Wierson & Forehand, 1994). Exasperated, they may then yell or gesture menacingly. When the child, now frightened, obeys, that reinforces the parents’ angry behavior. Over time, a destructive parent-child relationship develops.

To disrupt this cycle, parents should remember that basic rule of shaping: *Notice people doing something right and affirm them for it.* Give children attention and other reinforcers when they are behaving *well*. Target a specific

behavior, reward it, and watch it increase. When children misbehave or are defiant, don't yell at them or hit them. Simply explain the misbehavior and take away the iPad, remove a misused toy, or give a brief time-out.

TO CHANGE YOUR OWN BEHAVIOR Finally, we can use operant conditioning in our own lives. To reinforce your own desired behaviors (perhaps to improve your study habits) and extinguish the undesired ones (to stop smoking, for example), psychologists suggest taking these steps:

1. *State a realistic goal in measurable terms and announce it.* You might, for example, aim to boost your study time by an hour a day. To increase your commitment and odds of success, share that goal with friends.
2. *Decide how, when, and where you will work toward your goal.* Take time to plan. Those who specify how they will implement goals become more focused on those goals and more often fulfill them (Gollwitzer & Oettingen, 2012).
3. *Monitor how often you engage in your desired behavior.* You might log your current study time, noting under what conditions you do and don't study. (When we began writing textbooks, we each logged our time and were amazed to discover how much time we were wasting.)
4. *Reinforce the desired behavior.* To increase your study time, give yourself a reward (a snack or some activity you enjoy) only after you finish your extra hour of study. Agree with your friends that you will join them for weekend activities only if you have met your realistic weekly studying goal.
5. *Reduce the rewards gradually.* As your new behaviors become more habitual, give yourself a mental pat on the back instead of a cookie.

"I wrote another five hundred words. Can I have another cookie?"

RETRIEVAL PRACTICE

RP-12 Ethan constantly misbehaves at preschool even though his teacher scolds him repeatedly. Why does Ethan's misbehavior continue, and what can his teacher do to stop it?

ANSWER: If Ethan is seeking attention, the teacher's scolding may be reinforcing rather than punishing. To change Ethan's behavior, his teacher could offer reinforcement (such as praise) each time he behaves well. The teacher might encourage Ethan toward increasingly appropriate behavior through shaping, or by rephrasing rules as rewards instead of punishments. ("You can have a snack if you play nicely with the other children" [reward] rather than "You will not get a snack if you misbehave!" [punishment].)

Conditioning principles may also be applied in clinical settings. Explore some of these applications by engaging online with **Immersive Learning: How Would You Know If People Can Learn to Reduce Anxiety?**

Contrasting Classical and Operant Conditioning

LOQ 7-13 How does operant conditioning differ from classical conditioning?

Both classical and operant conditioning are forms of *associative learning*. Both involve *acquisition*, *extinction*, *spontaneous recovery*, *generalization*, and *discrimination*. But these two forms of learning also differ. Through classical (Pavlovian) conditioning, we associate different stimuli we do not control, and we respond automatically (*respondent behaviors*) ([TABLE 7.4](#)). Through operant conditioning, we associate our own behaviors—which act on our environment to produce rewarding or punishing stimuli (*operant behaviors*)—with their consequences.

TABLE 7.4
Comparison of Classical and Operant Conditioning

	Classical Conditioning	Operant Conditioning
<i>Basic idea</i>	Learning associations between events we do not control.	Learning associations between our behavior and its consequences.
<i>Response</i>	Involuntary, automatic.	Voluntary, operates on environment.
<i>Acquisition</i>	Associating events; NS is paired with US and becomes CS.	Associating a response with a consequence (reinforcer or punisher).
<i>Extinction</i>	CR decreases when CS is repeatedly presented alone.	Responding decreases when reinforcement stops.
<i>Spontaneous recovery</i>	The reappearance, after a rest period, of an extinguished CR.	The reappearance, after a rest period, of an extinguished response.
<i>Generalization</i>	The tendency to respond to	Responses learned in

	stimuli similar to the CS.	one situation occurring in other, similar situations.
<i>Discrimination</i>	Learning to distinguish between a CS and other stimuli that do not signal a US.	Learning that some responses, but not others, will be reinforced.

As we shall see next, our biology and cognitive processes influence both classical and operant conditioning.

“O! This learning, what a thing it is.”

William Shakespeare, *The Taming of the Shrew*, 1597

MASTER THE MATERIALS

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Thorndike's law of effect was the basis for _____'s work on operant conditioning and behavior control.

One way to change behavior is to reward natural behaviors in small steps, as the organism gets closer and closer to a desired behavior. This process is called _____.

Your dog is barking so loudly that it's making your ears ring. You clap your hands, the dog stops barking, your ears stop ringing, and you think to yourself, "I'll have to do that when he barks again." The end of the barking was for you a

- a. positive reinforcer.
- b. negative reinforcer.
- c. positive punishment.
- d. negative punishment.

How could your psychology instructor use negative reinforcement to encourage your attentive behavior during class?

Reinforcing a desired response only some of the times it occurs is called _____ reinforcement.

A restaurant is running a special deal. After you buy four meals at full price, your fifth meal will be free. This is an example of a _____ schedule of reinforcement.

- a. fixed-ratio
- b. variable-ratio
- c. fixed-interval
- d. variable-interval

The partial reinforcement schedule that reinforces a response after unpredictable time periods is a _____ - _____ schedule.

A medieval proverb notes that “a burnt child dreads the fire.” In operant conditioning, the burning would be an example of a

- a. primary reinforcer.
- b. negative reinforcer.
- c. punisher.
- d. positive reinforcer.

Biology, Cognition, and Learning

From drooling dogs, running rats, and pecking pigeons, we have learned much about the basic processes of learning. But conditioning principles don't tell us the whole story. Today's learning theorists recognize that learning is the product of the interaction of biological, psychological, and social-cultural influences ([FIGURE 7.12](#)).

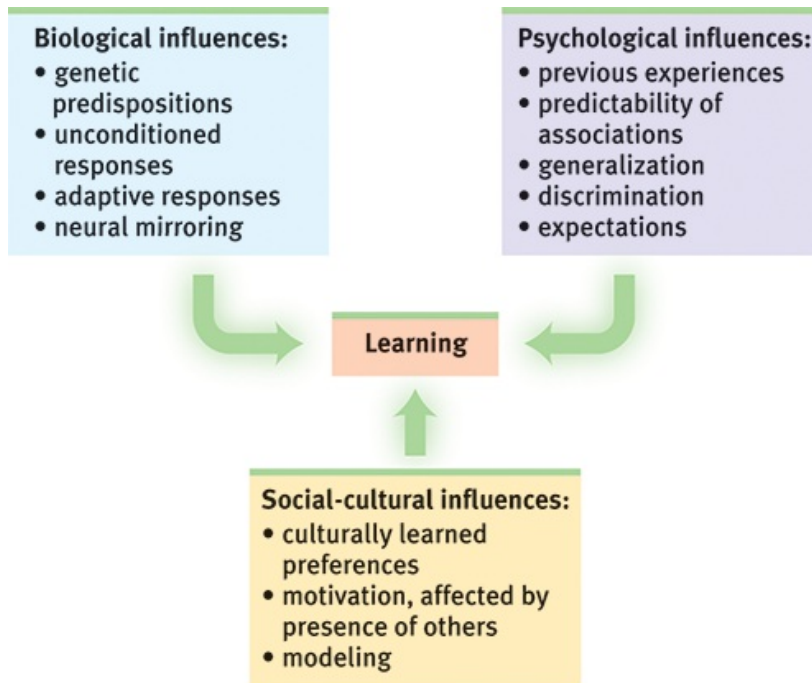

FIGURE 7.12 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 7.12 Biopsychosocial influences on learning

Our learning results not only from environmental experiences, but also from cognitive and biological influences.

Biological Constraints on Conditioning

LOQ 7-14 How do biological constraints affect classical and operant conditioning?

Ever since Charles Darwin, scientists have assumed that all animals share a common evolutionary history and thus share commonalities in their makeup and functioning. Pavlov and Watson, for example, believed the basic laws of learning were essentially similar in all animals. So it should make little difference whether one studied pigeons or people. Moreover, it seemed that any natural response could be conditioned to any neutral stimulus.

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

John Garcia

As the laboring son of California farmworkers, Garcia attended school only in the off-season during his early childhood years. After entering junior college in his late twenties, and earning his Ph.D. in his late forties, he received the American Psychological Association's Distinguished Scientific Contribution Award "for his highly original, pioneering research in conditioning and learning." He was also elected to the National Academy of Sciences.

Biological Limits on Classical Conditioning

In 1956, learning researcher Gregory Kimble proclaimed, "Just about any activity of which the organism is capable can be conditioned and . . . these responses can be conditioned to any stimulus that the organism can perceive" ([p. 195](#)). Twenty-five years later, he humbly acknowledged that "half a

thousand” scientific reports had proven him wrong (Kimble, 1981). More than the early behaviorists realized, an animal’s capacity for conditioning is limited by biological constraints. For example, each species’ predispositions *prepare* it to learn the associations that enhance its survival—a phenomenon called **preparedness**. Environments are not the whole story. Biology matters.

preparedness a biological predisposition to learn associations, such as between taste and nausea, that have survival value.

John Garcia was among those who challenged the prevailing idea that all associations can be learned equally well. While researching the effects of radiation on laboratory animals, Garcia and Robert Koelling (1966) noticed that rats began to avoid drinking water from the plastic bottles in radiation chambers. Could classical conditioning be the culprit? Might the rats have linked the plastic-tasting water (a CS) to the sickness (UR) triggered by the radiation (US)?

To test their hunch, Garcia and Koelling exposed the rats to a particular taste, sight, or sound (CS) and later also to radiation or drugs (US) that led to nausea and vomiting (UR). Two startling findings emerged: First, even if sickened as late as several hours after tasting a particular novel flavor, the rats thereafter avoided that flavor. This appeared to violate the notion that for conditioning to occur, the US must immediately follow the CS.

Second, the sickened rats developed aversions to tastes but not to sights or sounds. This contradicted the behaviorists’ idea that any perceivable stimulus could serve as a CS. But it made adaptive sense. For rats, the easiest way to identify tainted food is to taste it; if sickened after sampling a new food, they thereafter avoid it. This response, called *taste aversion*, makes it difficult to eradicate a population of “bait-shy” rats by poisoning.

Jose Oto/BSIP SA/Alamy

Taste aversion

If you became violently ill after eating oysters, you would probably have a hard time eating them again. Their smell and taste would have become a CS for nausea. This learning occurs readily because our biology prepares us to learn taste aversions to toxic foods.

Humans, too, seem biologically prepared to learn some associations rather than others. If you become violently ill four hours after eating contaminated oysters, you will probably develop an aversion to the *taste* of oysters more readily than to the sight of the associated restaurant, its plates, the people you were with, or the music you heard there. (In contrast, birds, which hunt by sight, appear biologically primed to develop aversions to the *sight* of tainted food [Nicolaus et al., 1983].)

Garcia's early findings on taste aversion were met with an onslaught of criticism. As the German philosopher Arthur Schopenhauer (1788–1860) once said, important ideas are first ridiculed, then attacked, and finally taken for granted. Leading journals refused to publish Garcia's work: The findings are impossible, said some critics. But, as sometimes happens in science,

Garcia and Koelling's oft-replicated taste-aversion research is now basic textbook material.

It is also a good example of experiments that begin with the discomfort of some laboratory animals and end by enhancing the welfare of many others. In one conditioned taste-aversion study, coyotes and wolves were tempted into eating sheep carcasses laced with a sickening poison. Thereafter, they developed an aversion to sheep meat; two wolves later penned with a live sheep seemed actually to fear it (Gustavson et al., 1974, 1976). These studies not only saved the sheep from their predators, but also saved the sheep-shunning coyotes and wolves from angry ranchers and farmers who had wanted to destroy them. Similar applications have prevented baboons from raiding African gardens, raccoons from attacking chickens, and ravens and crows from feeding on crane eggs. In all these cases, research helped preserve both the prey and their predators, all of which occupy an important ecological niche (Dingfelder, 2010; Garcia & Gustavson, 1997).

© blickwinkel/Alamy

Animal taste aversion

As an alternative to killing wolves and coyotes that preyed on sheep, some ranchers have sickened the animals with lamb laced with a drug to help them develop a taste aversion.

Such research supports Darwin's principle that natural selection favors traits that aid survival. Our ancestors who readily learned taste aversions were

unlikely to eat the same toxic food again and were more likely to survive and leave descendants. Nausea, like anxiety, pain, and other bad feelings, serves a good purpose. Like a low-oil warning on a car dashboard, each alerts the body to a threat (Davidson & Riley, 2015; Neese, 1991).

Our preparedness to associate a CS with a US that follows predictably and immediately is adaptive. Causes often do immediately precede effects. But as we saw in the taste-aversion findings, our predisposition to associate an effect with a preceding event can trick us. When chemotherapy triggers nausea and vomiting more than an hour following treatment, cancer patients may over time develop classically conditioned nausea (and sometimes anxiety) to the sights, sounds, and smells associated with the clinic (**FIGURE 7.13**) (Hall, 1997). Merely returning to the clinic's waiting room or seeing the nurses can provoke these conditioned feelings (Burish & Carey, 1986; Davey, 1992). Under normal circumstances, such revulsion to sickening stimuli would be adaptive.

RETRIEVAL PRACTICE

RP-14 How did Garcia and Koelling's taste-aversion studies help disprove Gregory Kimble's early claim that “just about any activity of which the organism is capable can be conditioned

. . . to any stimulus that the organism can perceive”?

ANSWER: Garcia and Koelling demonstrated that rats may learn an aversion to tastes, on which their survival depends, but not to sights or sounds.

“Once bitten, twice shy.”

G. F. Northall, *Folk-Phrases*, 1894

Biological Limits on Operant Conditioning

Nature also constrains each species’ capacity for operant conditioning. Science fiction writer Robert Heinlein (1907–1988) said it well: “Never try to teach a pig to sing; it wastes your time and annoys the pig.”

We most easily learn and retain behaviors that reflect our biological predispositions. Thus, using food as a reinforcer, you could easily condition a hamster to dig or to rear up, because these are among the animal’s natural food-searching behaviors. But you won’t be so successful if you use food as a reinforcer to shape face washing and other hamster behaviors that aren’t normally associated with food or hunger (Shettleworth, 1973). Similarly, you could easily teach pigeons to flap their wings to avoid being shocked, and to peck to obtain food: Fleeing with their wings and eating with their beaks are natural pigeon behaviors. However, pigeons would have a hard time learning to peck to avoid a shock, or to flap their wings to obtain food (Foree & LoLordo, 1973). The principle: *Biological constraints predispose organisms to learn associations that are naturally adaptive.*

For more information on animal behavior, see books by (we are not making this up) Robin Fox and Lionel Tiger.

In the early years of their work, animal trainers Marian Breland and Keller Breland presumed that operant principles would work on almost any response an animal could make. But along the way, they too learned about biological constraints. In one act, pigs trained to pick up large wooden “dollars” and

deposit them in a piggy bank began to drift back to their natural ways. They dropped the coin, pushed it with their snouts as pigs are prone to do, picked it up again, and then repeated the sequence—delaying their food reinforcer. This **instinctive drift** occurred as the animals reverted to their biologically predisposed patterns.

instinctive drift the tendency of learned behavior to gradually revert to biologically predisposed patterns.

Natural athletes

Animals can most easily learn and retain behaviors that draw on their biological predispositions, such as horses' inborn ability to move around obstacles with speed and agility.

Cognition's Influence on Conditioning

LOQ 7-15 How do cognitive processes affect classical and operant

conditioning?

Cognition and Classical Conditioning

In their dismissal of “mentalistic” concepts such as consciousness, Pavlov and Watson underestimated the importance of not only biological constraints such as preparedness and instinctive drift, but also the effects of cognitive processes (thoughts, perceptions, expectations). The early behaviorists believed that rats’ and dogs’ learned behaviors could be reduced to mindless mechanisms, so there was no need to consider cognition. But Robert Rescorla and Allan Wagner (1972) showed that an animal can learn the *predictability* of an event. If a shock always is preceded by a tone, and then may also be preceded by a light that accompanies the tone, a rat will react with fear to the tone but not to the light. Although the light is always followed by the shock, it adds no new information; the tone is a better predictor. The more predictable the association, the stronger the conditioned response. It’s as if the animal learns an *expectancy*, an awareness of how likely it is that the US will occur.

“All brains are, in essence, anticipation machines.”

Daniel C. Dennett, *Consciousness Explained*, 1991

Associations can influence attitudes (Hofmann et al., 2010). When British children viewed novel cartoon characters alongside either ice cream (*Yum!*) or brussels sprouts (*Yuck!*), they came to prefer the ice-cream-associated characters (Field, 2006). Other researchers have classically conditioned adults’ attitudes, using little-known Pokémon characters (Olson & Fazio, 2001). The participants were tasked with pressing a button whenever a specific target Pokémon character appeared on a video screen that displayed a stream of words and images. Unnoticed by the participants, when two other Pokémon characters appeared on the screen, one was consistently associated with positive words and images (such as *awesome* or a hot fudge sundae); the other appeared with negative words and images (such as *awful* or a cockroach). Later, they evaluated the extra Pokémon characters. Without any conscious memory of the pairings, the participants preferred the characters

associated with the positive stimuli.

Follow-up studies indicate that conditioned likes and dislikes are even stronger when people notice and are aware of the associations they have learned (Shanks, 2010). Cognition matters.

Such experiments help explain why classical conditioning treatments that ignore cognition often have limited success. For example, people receiving therapy for alcohol use disorder may be given alcohol spiked with a nauseating drug. Will they then associate alcohol with sickness? If classical conditioning were merely a matter of “stamping in” stimulus associations, we might hope so, and to some extent this does occur. However, one’s awareness that the nausea is induced by the drug, not the alcohol, often weakens the association between drinking alcohol and feeling sick, reducing the treatment’s effectiveness. So, even in classical conditioning, it is—especially with humans—not simply the CS-US association, but also the thought that counts.

Cognition and Operant Conditioning

B. F. Skinner acknowledged the biological underpinnings of behavior and the existence of private thought processes. Nevertheless, many psychologists criticized him for discounting cognition’s importance.

A mere eight days before dying of leukemia in 1990, Skinner stood before the American Psychological Association convention. In this final address, he still resisted the growing belief that cognitive processes (thoughts, perceptions, expectations) have a necessary place in the science of psychology and even in our understanding of conditioning. He viewed “cognitive science” as a throwback to early twentieth-century introspectionism. For Skinner, thoughts and emotions were behaviors that follow the same laws as other behaviors.

Nevertheless, the evidence of cognitive processes cannot be ignored. For example, animals on a *fixed-interval reinforcement schedule* respond more and more frequently as the time approaches when a response will produce a reinforcer. Although a strict behaviorist would object to talk of “expectations,” the animals behave as if they expected that repeating the response would soon produce the reward.

Evidence of cognitive processes has also come from studying rats in

mazes. Rats exploring a maze, given no obvious rewards, seem to develop a **cognitive map**, a mental representation of the maze. When an experimenter then places food in the maze's goal box, these rats run the maze as quickly as other rats that were previously reinforced with food for this result. Like people sightseeing in a new town, the exploring rats seemingly experienced **latent learning** during their earlier tours. That learning became apparent only when there was some incentive to demonstrate it. Children, too, may learn from watching a parent but demonstrate the learning only much later, as needed.

cognitive map a mental representation of the layout of one's environment. For example, after exploring a maze, rats act as if they have learned a cognitive map of it.

latent learning learning that occurs but is not apparent until there is an incentive to demonstrate it.

"Bathroom? Sure, it's just down the hall to the left, jog right, left, another left, straight past two more lefts, then right, and it's at the end of the third corridor on your right."

The New Yorker Collection, 2000, Pat Byrnes, from cartoonbank.com. All Rights Reserved.

The point to remember: There is more to learning than associating a response with a consequence; there is also cognition. In [Chapter 9](#) we will encounter more striking evidence of animals' cognitive abilities in solving problems and in using aspects of language.

The cognitive perspective has also shown us the limits of rewards: Promising people a reward for a task they already enjoy can backfire. Excessive rewards can destroy **intrinsic motivation**—the desire to perform a behavior effectively and for its own sake. In experiments, children have been promised a payoff for playing with an interesting puzzle or toy. Later, they played with the toy *less* than did unpaid children (Deci et al., 1999; Tang & Hall, 1995). Likewise, rewarding children with toys or candy for reading diminishes the time they spend reading (Marinak & Gambrell, 2008). It is as if they think, “If I have to be bribed into doing this, it must not be worth doing for its own sake.”

intrinsic motivation a desire to perform a behavior effectively for its own sake.

To sense the difference between intrinsic motivation and **extrinsic motivation** (behaving in ways that gain external rewards or avoid punishment), think about your experience in this course. Are you feeling pressured to finish this reading before a deadline? Worried about your grade? Eager for the credits that will count toward graduation? If Yes, then you are extrinsically motivated (as, to some extent, almost all students must be). Are you also finding the material interesting? Does learning it make you feel more competent? If there were no grade at stake, might you be curious enough to want to learn the material for its own sake? If Yes, intrinsic motivation also fuels your efforts.

extrinsic motivation a desire to perform a behavior to receive promised rewards or avoid threatened punishment.

Youth sports coaches who aim to promote enduring interest in an activity, not just to pressure players into winning, focus on the intrinsic joys of playing and reaching one’s potential (Deci & Ryan, 1985, 2009). Doing so may also lead to greater rewards. Students who focus on learning (intrinsic reward) often get good grades and graduate (extrinsic rewards). Doctors who focus on healing (intrinsic) may make a good living (extrinsic). Indeed,

research suggests that people who focus on their work’s meaning and significance not only do better work but ultimately earn more extrinsic rewards (Wrzesniewski et al., 2014).

Will & Deni McIntyre/Science Source

Latent learning

Animals, like people, can learn from experience, with or without reinforcement. In a classic experiment, rats in one group repeatedly explored a maze, always with a food reward at the end. Rats in another group explored the maze with no food reward. But once given a food reward at the end, rats in the second group thereafter ran the maze as quickly as (and even faster than) the always-rewarded rats (Tolman & Honzik, 1930).

Nevertheless, extrinsic rewards used to signal a job well done (rather than to bribe or control someone) can be effective (Boggiano et al., 1985). “Most improved player” awards, for example, can boost feelings of competence and increase enjoyment of a sport. Rightly administered, rewards can improve performance and spark creativity (Eisenberger & Aselage, 2009; Henderlong & Lepper, 2002). And the rewards that often follow academic achievement, such as scholarships and jobs, are here to stay.

[TABLE 7.5](#) compares the biological and cognitive influences on classical and operant conditioning.

TABLE 7.5
Biological and Cognitive Influences on Conditioning

--	--	--

	Classical Conditioning	Operant Conditioning
<i>Biological influences</i>	Natural predispositions constrain what stimuli and responses can easily be associated.	Organisms most easily learn behaviors similar to their natural behaviors; unnatural behaviors instinctively drift back toward natural ones.
<i>Cognitive influences</i>	Organisms develop an expectation that CS signals the arrival of US.	Organisms develop an expectation that a response will be reinforced or punished; they also exhibit latent learning, without reinforcement.

RETRIEVAL PRACTICE

RP-15 Instinctive drift and latent learning are examples of what important idea?

ANSWER: The success of operant conditioning is affected not just by environmental cues, but also by biological and cognitive factors.

Learning by Observation

LOQ 7-16 How does observational learning differ from associative learning? How may observational learning be enabled by neural mirroring?

Cognition supports [observational learning](#), in which higher animals, especially humans, learn without direct experience, by watching and imitating others. A child who sees his sister burn her fingers on a hot stove learns not to touch it. We learn our native languages and various other specific behaviors by observing and imitating others, a process called [modeling](#).

observational learning learning by observing others.

modeling the process of observing and imitating a specific behavior.

Picture this scene from an experiment by Albert Bandura, the pioneering researcher of observational learning (Bandura et al., 1961): A preschool child works on a drawing. An adult in another part of the room builds with Tinkertoys. As the child watches, the adult gets up and for nearly 10 minutes pounds, kicks, and throws around the room a large inflated Bobo doll, yelling, “Sock him in the nose. . . . Hit him down. . . . Kick him.”

The child is then taken to another room filled with appealing toys. Soon the experimenter returns and tells the child she has decided to save these good toys “for the other children.” She takes the now-frustrated child to a third room containing a few toys, including a Bobo doll. Left alone, what does the child do?

Compared with children not exposed to the adult model, those who viewed the model’s actions were more likely to lash out at the doll. Observing the aggressive outburst apparently lowered their inhibitions. But *something more* was also at work, for the children imitated the very acts they had observed and used the very words they had heard ([FIGURE 7.14](#)).

FIGURE 7.14 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
© Albert Bandura, Dept. of Psychology, Stanford University

FIGURE 7.14 The famous Bobo doll experiment

Notice how the children’s actions directly imitate the adult’s.

For 3 minutes of classic footage, see the Video: Bandura’s Bobo Doll Experiment.

That “something more,” Bandura suggests, was this: By watching models,

we experience *vicarious reinforcement* or *vicarious punishment*, and we learn to anticipate a behavior's consequences in situations like those we are observing. We are especially likely to learn from people we perceive as similar to ourselves, as successful, or as admirable. fMRI scans show that when people observe someone winning a reward (and especially when it's someone likable and similar to themselves), their own brain reward systems activate, much as if they themselves had won the reward (Mobbs et al., 2009). When we identify with someone, we experience their outcomes vicariously. Even our learned fears may extinguish as we observe another safely navigating the feared situation (Golkar et al., 2013). Lord Chesterfield (1694–1773) had the idea: “We are, in truth, more than half what we are by imitation.”

Bandura's work provides an example of how basic research “pursued for its own sake” can have a broader purpose. “The Bobo Doll studies,” he reflected (2016), “provided the principles for unforeseen global applications 25 years later.” Insights derived from his research have not only been used to restrain televised violence, but also to offer social models that have helped reduce unplanned childbearing, protect against AIDS, and promote environmental conservation.

Polaris/Newscom

Albert Bandura

“The Bobo doll follows me wherever I go. The photographs are published in every introductory psychology text and virtually every undergraduate takes introductory psychology. I recently checked into a Washington hotel. The clerk at the desk asked, ‘Aren’t you the psychologist who did the Bobo doll experiment?’ I answered, ‘I am afraid that will be my legacy.’ He replied, ‘That deserves an upgrade. I will put you in a suite in the quiet part of the hotel’” (2005). A recent analysis of citations, awards, and textbook coverage identified Bandura—shown here receiving a 2016 U.S. National Medal of Science from President Obama—as the world’s most eminent psychologist (Diener et al., 2014).

Mirrors and Imitation in the Brain

In 1991, on a hot summer day in Parma, Italy, a lab monkey awaited its researchers’ return from lunch. The researchers had implanted wires next to its motor cortex, in a frontal lobe brain region that enabled the monkey to plan and enact movements. The monitoring device would alert the

researchers to activity in that region of the monkey's brain. When the monkey moved a peanut into its mouth, for example, the device would buzz. That day, as one of the researchers reentered the lab, ice cream cone in hand, the monkey stared at him. As the researcher raised the cone to lick it, the monkey's monitor buzzed—as if the motionless monkey had itself moved (Blakeslee, 2006; Iacoboni, 2008, 2009).

The same buzzing had been heard earlier, when the monkey watched humans or other monkeys move peanuts to their mouths. The flabbergasted researchers, led by Giacomo Rizzolatti (2002, 2006), had, they believed, stumbled onto a previously unknown type of neuron. These presumed [mirror neurons](#), they argued, provide a neural basis for everyday imitation and observational learning. When a monkey grasps, holds, or tears something, these neurons fire. And they likewise fire when the monkey observes another doing so. When one monkey sees, its neurons mirror what another monkey does. (For a debate regarding the importance of mirror neurons, which are sometimes overblown in the popular press, see Gallese et al., 2011; Hickok, 2014.)

mirror neurons frontal lobe neurons that some scientists believe fire when we perform certain actions or observe another doing so. The brain's mirroring of another's action may enable imitation and empathy.

Imitation is widespread in other species. Chimpanzees observe and imitate all sorts of novel foraging and tool use behaviors, which are then transmitted from generation to generation within their local culture (Hopper et al., 2008; Whiten et al., 2007). In one 27-year analysis of 73,790 humpback whale observations, a single whale in 1980 whacked the water to drive prey fish into a clump. In the years since, this “lobtail” technique spread among other whales (Allen et al., 2013).

David Sipress

Mirror neurons at work?

“Your back is killing me!”

Masa Ushioda/AGE Fotostock; Erica van de Waal

Animal social learning

Whacking the water to boost feeding has spread among humpback whales through social learning (Allen et al., 2013). Likewise, monkeys learn to prefer whatever color corn they observe other monkeys eating.

So, too, with monkeys. Erica van de Waal and her co-researchers (2013) trained groups of vervet monkeys to prefer either blue or pink corn by soaking one color in a disgusting-tasting solution. Four to six months later, after a new generation of monkeys was born, the adults stuck with whatever color they had learned to prefer—and, on observing them, so did all but one of 27 infant monkeys. Moreover, when blue- (or pink-) preferring males migrated to the other group, they switched preferences and began eating as the other group did. Monkey see, monkey do.

In humans, imitation is pervasive. Our catchphrases, fashions, ceremonies, foods, traditions, morals, and fads all spread by one person copying another. Children and even infants are natural imitators (Marshall & Meltzoff, 2014). By 8 to 16 months, infants imitate various novel gestures (Jones, 2007). By 12 months ([FIGURE 7.15](#)), they look where an adult is looking (Meltzoff et

al., 2009). And by 14 months, children imitate acts modeled on TV (Meltzoff, 1988; Meltzoff & Moore, 1989, 1997). Even as 2½-year-olds, when many of their mental abilities are near those of adult chimpanzees, young humans surpass chimps at social tasks such as imitating another's solution to a problem (Herrmann et al., 2007). Children see, children do.

FIGURE 7.15 Myers/DeWall, *Psychology*, 12e. © 2018 Worth Publishers
Meltzoff, A. N., Kuhl, P. K., Movellan, J. & Sejnowski, T. J. (2009). Foundations for a new science of learning. *Science*, 325, 284–288.

FIGURE 7.15 Imitation

This 12-month-old infant sees an adult look left, and immediately follows her gaze (Meltzoff et al., 2009).

“This instinct to humiliate, when it’s modeled by someone in the public platform, by someone powerful, it filters down into everybody’s life, because it . . . gives permission for other people to do the same thing.”

Meryl Streep, U.S. Golden Globe Award speech, 2017

So strong is the human predisposition to learn from watching adults that 2- to 5-year-old children *overimitate*. Whether living in urban Australia or rural Africa, they copy even irrelevant adult actions. Before reaching for a toy in a plastic jar, they will first stroke the jar with a feather if that’s what they have observed (Lyons et al., 2007). Or, imitating an adult, they will wave a stick over a box and then use the stick to push on a knob that opens the box—when all they needed to do to open the box was to push on the knob (Nielsen & Tomaselli, 2010).

“Children need models more than they need critics.”

Joseph Joubert, *Pensées*, 1842

Humans, like monkeys, have brains that support empathy and imitation. Researchers cannot insert experimental electrodes in human brains, but they can use fMRI scans to see brain activity associated with performing and with

observing actions. So, is the human capacity to simulate another's action and to share in another's experience due to specialized mirror neurons? Or is it due to distributed brain networks? That issue is under debate (Fox et al., 2016; Gallese et al. 2011; Hickok, 2014; Iacoboni, 2008, 2009; Spaulding, 2013). Regardless, children's brains do enable their empathy and their ability to infer another's mental state, an ability known as *theory of mind*.

Our brain's response to observing others makes emotions contagious. Our brain simulates and vicariously experiences what we observe. So real are these mental instant replays that we may misremember an action we have observed as one we have performed (Lindner et al., 2010). But through these reenactments, we grasp others' states of mind. Observing others' postures, faces, voices, and writing styles, we unconsciously synchronize our own to theirs—which helps us feel what they are feeling (Bernieri et al., 1994; Ireland & Pennebaker, 2010). Imitation helps us gain friends, leading us to mimic those we like (Chartrand & Lakin, 2013). We find ourselves yawning when they yawn, smiling when they smile, laughing when they laugh.

Seeing a loved one's pain, our faces mirror the other's emotion. But as [FIGURE 7.16](#) shows, so do our brains. In this fMRI scan, the pain imagined by an empathic romantic partner has triggered some of the same brain activity experienced by the loved one actually having the pain (Singer et al., 2004). Even fiction reading may trigger such activity, as we mentally simulate (and vicariously experience) the experiences described (Mar & Oatley, 2008; Speer et al., 2009). In one experiment, university students read (and vicariously experienced) a fictional fellow student's description of overcoming obstacles to vote. A week later, those who read the first-person account were more likely to vote in a presidential primary election (Kaufman & Libby, 2012). In other studies, students who read *Harry Potter* (the bestselling kid wizard series that masterfully modeled tolerance), reported less prejudice against immigrants, refugees, and gay people (Vezzali et al., 2015).

FIGURE 7.16 Experienced and imagined pain in the brain

Brain activity related to actual pain (left) is mirrored in the brain of an observing loved one (right). Empathy in the brain shows up in emotional brain areas, but not in the somatosensory cortex, which receives the physical pain input.

Applications of Observational Learning

LOQ 7-17 What is the impact of prosocial modeling and of antisocial modeling?

The big news from Bandura's studies and mirror-neuron research is that we look, we mentally imitate, and we learn. Models—in our family, our neighborhood, or the media we consume—may have effects, good and bad.

PROSOCIAL EFFECTS The good news is that people's modeling of prosocial (positive, helpful) behaviors can have prosocial effects. Many business organizations effectively use *behavior modeling* to help new employees learn communications, sales, and customer service skills (Taylor et al., 2005). Trainees gain these skills faster when they are able to observe the skills being modeled effectively by experienced workers (or actors simulating them).

prosocial behavior positive, constructive, helpful behavior. The opposite of antisocial behavior.

People who exemplify nonviolent, helpful behavior can also prompt similar behavior in others. After observing someone helping (assisting a

woman with dropped books), people become more helpful, such as by assisting someone who dropped a dollar (Burger et al., 2015). India's Mahatma Gandhi and America's Martin Luther King, Jr., both drew on the power of modeling, making nonviolent action a powerful force for social change in both countries (Matsumoto et al., 2015). The media offer models. For example, one research team found that across seven countries, viewing prosocial TV, movies, and video games boosted later helping behavior (Prot et al., 2014).

Zumapress/Newscom

A model caregiver

This girl is learning orphan-nursing skills, as well as compassion, by observing her mentor in this Humane Society program. As the sixteenth-century proverb states, “Example is better than precept.”

Parents are also powerful models. European Christians who risked their lives to rescue Jews from the Nazis usually had a close relationship with at least one parent who modeled a strong moral or humanitarian concern; this was also true for U.S. civil rights activists in the 1960s (London, 1970; Oliner & Oliner, 1988). The observational learning of morality begins early. Socially responsive toddlers who readily imitate their parents tend to become preschoolers with a strong internalized conscience (Forman et al., 2004).

Models are most effective when their actions and words are consistent. To encourage children to read, read to them and surround them with books and people who read. To increase the odds that your children will practice your religion, worship and attend religious activities with them. Sometimes, however, models say one thing and do another. Many parents seem to operate according to the principle “Do as I say, not as I do.” Experiments suggest that children learn to do both (Rice & Grusec, 1975; Rushton, 1975). Exposed to

a hypocrite, they tend to imitate the hypocrisy—by doing what the model did and saying what the model said.

David Strickler/The Image Works

Children see, children do?

Children who often experience physical punishment tend to display more aggression.

RETRIEVAL PRACTICE

RP-16 Jason's parents and older friends all drive over the speed limit, but they advise him not to. Juan's parents and friends drive within the speed limit, but they say nothing to deter him from speeding. Will Jason or Juan be more likely to speed?

ANSWER: Jason may be more likely to speed. Observational learning studies suggest that children tend to do as others do and say what they say.

ANTISOCIAL EFFECTS The bad news is that observational learning may also have *antisocial effects*. This helps us understand why abusive parents

might have aggressive children, why children who are lied to become more likely to cheat and lie, and why many men who beat their wives had wife-battering fathers (Hays & Carver, 2014; Stith et al., 2000). Critics note that such aggressiveness could be genetic. But with monkeys, we know it can be environmental. In study after study, young monkeys separated from their mothers and subjected to high levels of aggression grew up to be aggressive themselves (Chamove, 1980). The lessons we learn as children are not easily replaced as adults, and they are sometimes visited on future generations.

“The problem with television is that the people must sit and keep their eyes glued to a screen: The average American family hasn’t time for it. Therefore the showmen are convinced that . . . television will never be a serious competitor of [radio] broadcasting.”

The New York Times, 1939

TV shows, movies, and online videos are sources of observational learning. While watching, children may learn that bullying is an effective way to control others, that free and easy sex brings pleasure without later misery or disease, or that men should be tough and women gentle. And they have ample time to learn such lessons. During their first 18 years, most children in developed countries spend more time watching TV than they spend in school. The average teen watches more than 4 hours a day; the average adult, 3 hours (Robinson & Martin, 2009; Strasburger et al., 2010).

Screen time’s greatest effect may stem from what it displaces. Children and adults who spend several hours a day in front of a screen spend that many fewer hours in other pursuits—talking, studying, playing, reading, or socializing face-to-face with friends. What would you have done with your extra time if you had spent even half as many hours in front of a screen? How might you be different as a result?

Viewers are learning about life from a peculiar storyteller, one that reflects the culture’s mythology rather than its reality. Between 1998 and 2006, prime-time violence on TV reportedly increased 75 percent (PTC, 2007). An analysis of more than 3000 network and cable programs aired during one

closely studied year revealed that nearly 6 in 10 featured violence, that 74 percent of the violence went unpunished, that 58 percent did not show the victims' pain, that nearly half the incidents involved "justified" violence, and that nearly half involved an attractive perpetrator. These conditions define the recipe for the *violence-viewing effect* described in many studies and recognized by a near-consensus of media researchers (Bushman et al., 2015; Donnerstein, 1998, 2011).

In 2012, a well-armed man targeted young children and their teachers in a horrifying mass shooting at Connecticut's Sandy Hook Elementary School. Was the American media correct in wondering whether the killer was influenced by the violent video games found stockpiled in his home? (See [Thinking Critically About: The Effects of Viewing Media Violence](#).)

Thinking Critically About: The Effects of Viewing Media Violence

LOO 7-18 What is the violence-viewing effect?

Introduction of TV, 1957-1974

Doubling of homicide rate in U.S. and Canada¹

Introduction of TV for White South Africans in 1975

Near-doubling of homicide rate in South Africa²

Heavy exposure to media violence for U.S. 9-11-year-olds

Increased fighting, and more violent behavior later as teens²

BUT, CORRELATION ≠ CAUSATION!

Experimental studies have also found that media violence viewing can cause aggression: Viewing violence (compared to entertaining nonviolence) → participants react more cruelly when provoked. (Effect is strongest if the violent person is attractive, the violence seems justified and realistic, the act goes unpunished, and the viewer does not see pain or harm caused.)

What prompts the violence-viewing effect?

1 IMITATION:

Watching violent cartoons → Sevenfold increase in violent play³

Limited exposure to violent programs → Reduced aggressive behavior⁴

2 DESENSITIZATION:

Prolonged exposure to violence → Viewers are later indifferent (desensitized) to violence on TV or in real life.⁵

Adult males spent 3 evenings watching sexually violent movies. → Viewers became progressively less bothered by the violence shown. Compared to a control group, they expressed less sympathy for domestic violence victims and rated victims' injuries as less severe.⁶

Violent moviegoers → less likely to help
Nonviolent moviegoers → more likely to help⁷

• APA Task Force on Violent Media (2015) found that the "research demonstrates a consistent relation between violent video game use and increases in aggressive behavior, aggressive cognitions, and aggressive affect, and decreases in prosocial behavior, empathy, and sensitivity to aggression."

• American Academy of Pediatrics (2009) has advised pediatricians that "media violence can contribute to aggressive behavior, desensitization to violence, nightmares, and fear of being harmed."

"Thirty seconds worth of glorification of a soap bar sells soap. Twenty-five minutes worth of glorification of violence sells violence."

* * *

Our knowledge of learning principles comes from the work of hundreds of investigators. This chapter has focused on the ideas of a few pioneers—Ivan Pavlov, John Watson, B. F. Skinner, and Albert Bandura. They illustrate the impact that can result from single-minded devotion to a few well-defined problems and ideas. These researchers defined the issues and impressed on us the importance of learning. As their legacy demonstrates, intellectual history is often made by people who risk going to extremes in pushing ideas to their limits (Simonton, 2000).

RETRIEVAL PRACTICE

RP-17 Match the examples (1–5) to the appropriate underlying learning principle (a–e):

- a. Classical conditioning
 - b. Operant conditioning
 - c. Latent learning
 - d. Observational learning
 - e. Biological predispositions
1. Knowing the way from your bed to the bathroom in the dark
 2. Your little brother getting in a fight after watching a violent action movie
 3. Salivating when you smell brownies in the oven
 4. Disliking the taste of chili after becoming violently sick a few hours after eating chili
 5. Your dog racing to greet you on your arrival home

ANSWER: 1. c, 2. d, 3. a, 4. e, 5. b

REVIEW **Biology, Cognition, and Learning**

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Garcia and Koelling's _____ - _____ studies showed that conditioning can occur even when the unconditioned stimulus (US) does not immediately follow the neutral stimulus (NS).

Taste-aversion research has shown that some animals develop aversions to certain tastes but not to sights or sounds. What evolutionary psychology finding does this support?

Evidence that cognitive processes play an important role in learning comes in part from studies in which rats running a maze develop a _____ of the maze.

Rats that explored a maze without any reward were later able to run the maze as well as other rats that had received food rewards for running the maze. The rats that had learned without reinforcement demonstrated _____.

Children learn many social behaviors by imitating parents and other models. This type of learning is called _____.

According to Bandura, we learn by watching models because we experience _____ reinforcement or _____ punishment.

Parents are most effective in getting their children to imitate them if

- a. their words and actions are consistent.
- b. they have outgoing personalities.
- c. one parent works and the other stays home to care for the children.
- d. they carefully explain why a behavior is acceptable in adults but not in children.

Some scientists believe that the brain has _____ neurons that enable empathy and imitation.

Most experts agree that repeated viewing of media violence

- a. makes all viewers significantly more aggressive.

- o. has little effect on viewers.
- p. is a risk factor for viewers' increased aggression.
- l. makes viewers angry and frustrated.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Encoding Memories

Storing and Retrieving Memories

Memory Storage

Memory Retrieval

Forgetting, Memory Construction, and Improving Memory

Forgetting

Memory Construction Errors

THINKING CRITICALLY ABOUT: Can Memories of Childhood Sexual Abuse Be Repressed and Then Recovered?

Improving Memory

Be thankful for memory. We take it for granted, except when it malfunctions. But it is our memory that accounts for time and defines our life. It is our memory that enables us to recognize family, speak our language, and find our way home. It is our memory that enables us to enjoy an experience and then mentally replay and enjoy it again. It is our memory that enables us to build histories with those we love. And it is our memory that occasionally pits us against those whose offenses we cannot forget. Our shared memories help bind us together as Irish or Icelandic, Serbian or Samoan.

In large part, we are what we remember. Without memory—our storehouse of accumulated learning—there would be no savoring of past joys, no guilt or anger over painful recollections. We would instead live in an enduring present, each moment fresh. Each person would be a stranger, every language foreign, every task—dressing, cooking, biking—a new challenge. You would even be a stranger to yourself, lacking that continuous sense of self that extends from your distant past to your momentary present.

Researchers study memory from many perspectives. We'll begin by looking at the measuring, modeling, and encoding of memories, and we will examine how memories are stored and retrieved. Then we'll explore what happens when our memories fail us, and look at ways to improve memory.

Studying and Encoding Memories

Studying Memory

LOQ **LEARNING OBJECTIVE QUESTION** **8.1** What is *memory*, and how is it measured?

Memory is learning that persists over time; it is information that has been acquired and stored and can be retrieved. Research on memory's extremes has helped us understand how memory works. At age 92, my [DM's] father suffered a small stroke that had but one peculiar effect. He was as mobile as before. His genial personality was intact. He knew us and enjoyed poring over family photo albums and reminiscing about his past. But he had lost most of his ability to lay down new memories of conversations and everyday episodes. He could not tell me what day of the week it was, or what he'd had for lunch. Told repeatedly of his brother-in-law's recent death, he was surprised and saddened each time he heard the news.

memory the persistence of learning over time through the encoding, storage, and retrieval of information.

Some disorders slowly strip away memory. *Alzheimer's disease* begins as difficulty remembering new information and progresses into an inability to do everyday tasks. Family members and close friends become strangers; complex speech becomes simple sentences; the brain's memory centers, once strong, become weak and wither away (Desikan et al., 2009). Over several years, someone with Alzheimer's may become unknowing and unknowable. Lost memory strikes at the core of our humanity, leaving people robbed of a sense of joy, meaning, and companionship.

Extreme forgetting

Alzheimer's disease severely damages the brain, and in the process strips away memory.

At the other extreme are people who would win gold medals in a memory Olympics. Russian journalist Solomon Shereshevskii, or S, had merely to listen while other reporters scribbled notes (Luria, 1968). The average person could parrot back a string of about 7—maybe even 9—digits. S could repeat up to 70, if they were read about 3 seconds apart in an otherwise silent room. Moreover, he could recall digits or words backward as easily as forward. His accuracy was unerring, even when recalling a list 15 years later. “Yes, yes,” he might recall. “This was a series you gave me once when we were in your apartment. . . . You were sitting at the table and I in the rocking chair. . . . You were wearing a gray suit. . . .”

Amazing? Yes, but consider your own impressive memory. You remember countless faces, places, and happenings; tastes, smells, and textures; voices, sounds, and songs. In one study, students listened to snippets—a mere four-tenths of a second—from popular songs. How often did they recognize the artist and song? More than 25 percent of the time (Krumhansl, 2010). We often recognize songs as quickly as we recognize a familiar voice.

So, too, with faces and places. Imagine viewing more than 2500 slides of faces and places for 10 seconds each. Later, you see 280 of these slides, paired with others you've never seen. Actual participants in this experiment recognized 90 percent of the slides they had viewed in the first round (Haber, 1970). In a follow-up experiment, people exposed to 2800 images for only 3

seconds each spotted the repeats with 82 percent accuracy (Konkle et al., 2010). Look for a target face in a sea of faces and you later will recognize other faces from the scene as well (Kaunitz et al., 2016). Some super-recognizers display an extraordinary ability to recognize faces. Eighteen months after viewing a video of an armed robbery, one such police officer spotted and arrested the robber walking on a busy street (Davis et al., 2013). And it's not just humans who have shown remarkable memory for faces. Sheep can learn to remember faces ([FIGURE 8.1](#)). And so can at least one fish species—as demonstrated by their spitting at familiar faces to trigger a food reward (Newport et al., 2016).

FIGURE 8.1 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Eric Isselee/Shutterstock

FIGURE 8.1 Other animals also display face smarts

After food rewards are repeatedly associated with some sheep faces, but not with others, sheep remember the food-associated faces for two years (Kendrick & Feng, 2011).

How do we humans accomplish such memory feats? How does our brain pluck information out of the world around us and tuck that information away for later use? How can we remember things we have not thought about for years, yet forget the name of someone we just met? How are memories stored in our brain? Why will you be likely, later in this chapter, to misrecall this sentence: “*The angry rioter threw the rock at the window*”? In this chapter, we’ll consider these fascinating questions and more.

“If any one faculty of our nature may be called *more* wonderful than the rest, I do think it is memory.”

Jane Austen, *Mansfield Park*, 1814

Measuring Retention

To a psychologist, evidence that learning persists includes these three *measures of retention*:

- **recall**—*retrieving* information that is not currently in your conscious awareness but that was learned at an earlier time. A fill-in-the-blank question tests your recall.
- **recognition**—*identifying* items previously learned. A multiple-choice question tests your recognition.
- **relearning**—*learning something more quickly* when you learn it a second or later time. When you study for a final exam or engage a language used in early childhood, you will relearn the material more easily than you did initially.

recall a measure of memory in which the person must retrieve information learned earlier, as on a fill-in-the-blank test.

recognition a measure of memory in which the person identifies items previously learned, as on a multiple-choice test.

relearning a measure of memory that assesses the amount of time saved when learning material again.

Long after you cannot recall most of the people in your high school graduating class, you may still be able to recognize their yearbook pictures and spot their names in a list of names. In one experiment, people who had graduated 25 years earlier could not recall many of their old classmates. But they could *recognize* 90 percent of their pictures and names (Bahrack et al., 1975). If you are like most students, you, too, could probably recognize more

names of Snow White's seven dwarfs than you could recall (Miserandino, 1991).

Our recognition memory is impressively quick and vast. "Is your friend wearing a new or old outfit?" "Old." "Is this five-second movie clip from a film you've ever seen?" "Yes." "Have you ever seen this person before—this minor variation on the same old human features (two eyes, one nose, and so on)?" "No." Before the mouth can form our answer to any of millions of such questions, the mind knows, and knows that it knows.

Our response speed when recalling or recognizing information indicates memory strength, as does our speed at *relearning*. Pioneering memory researcher Hermann Ebbinghaus (1850–1909) showed this over a century ago, using nonsense syllables. He randomly selected a sample of syllables, practiced them, and tested himself. To get a feel for his experiments, rapidly read aloud, eight times over, the following list (from Baddeley, 1982), then look away and try to recall the items:

JIH, BAZ, FUB, YOX, SUJ, XIR, DAX, LEQ, VUM, PID, KEL, WAV, TUV, ZOF, GEK, HIW.

The day after learning such a list, Ebbinghaus could recall few of the syllables. But they weren't entirely forgotten. As [FIGURE 8.2](#) portrays, the more frequently he repeated the list aloud on Day 1, the less time he required to relearn the list on Day 2. Additional rehearsal (overlearning) of verbal information increases retention, especially when practice is distributed over time. For students, this means that it helps to rehearse course material even after you know it.

FIGURE 8.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.2 Ebbinghaus' retention curve

Ebbinghaus found that the more times he practiced a list of nonsense syllables on Day 1, the less time he required to relearn it on Day 2. Speed of relearning is one measure of memory retention. (From Baddeley, 1982.)

National News/ZUMAPRESS.com/Newscom;
Seth Poppel Yearbook Library

Remembering things past

Even if Taylor Swift and Bruno Mars had not become famous, their high school classmates would most likely still recognize them in these photos.

The point to remember: Tests of recognition and of time spent relearning demonstrate that we remember more than we can recall.

RETRIEVAL PRACTICE

RP-1 Multiple-choice questions test our _____. Fill-in-the-blank questions test our _____.

ANSWER: recognition; recall.

RP-2 If you want to be sure to remember what you're learning for an upcoming test, would it be better to use *recall* or *recognition* to check your memory? Why?

ANSWER: It would be better to test your memory with *recall* (such as with short-answer or fill-in-the-blank self-test questions) rather than *recognition* (such as with multiple-choice questions). Recalling information is harder than recognizing it. So if you can recall it, that means your retention of the material is better than if you could only recognize it. Your chances of test success are therefore greater.

Memory Models

LOQ 8-2 How do psychologists describe the human memory system?

Architects make virtual house models to help clients imagine their future homes. Similarly, psychologists create memory models that, even if imperfect, are useful. Such models help us think about how our brain forms and retrieves memories. An *information-processing model* likens human memory to computer operations. Thus, to remember any event, we must

- get information into our brain, a process called [encoding](#).
 - retain that information, a process called [storage](#).
 - later get the information back out, a process called [retrieval](#).
-

encoding the process of getting information into the memory system—for example, by extracting meaning.

storage the process of retaining encoded information over time.

retrieval the process of getting information out of memory storage.

Like all analogies, computer models have their limits. Our memories are less literal and more fragile than a computer's. Most computers also process information sequentially, even while alternating between tasks. Our agile brain processes many things simultaneously (some of them unconsciously) by means of [parallel processing](#). To focus on this multitrack processing, one information-processing model, *connectionism*, views memories as products of interconnected neural networks. Specific memories arise from particular activation patterns within these networks. Every time you learn something new, your brain's neural connections change, forming and strengthening pathways that allow you to interact with and learn from your constantly changing environment.

parallel processing processing many aspects of a problem simultaneously; the brain's natural mode of information processing for many functions.

To explain our memory-forming process, Richard Atkinson and Richard Shiffrin (1968, 2016) proposed a three-stage model:

1. We first record to-be-remembered information as a fleeting [sensory memory](#).
2. From there, we process information into [short-term memory](#), where we encode it through *rehearsal*.
3. Finally, information moves into [long-term memory](#) for later retrieval.

sensory memory the immediate, very brief recording of sensory information in the memory system.

short-term memory activated memory that holds a few items briefly, such as digits of a phone number while calling, before the information is stored or forgotten.

long-term memory the relatively permanent and limitless storehouse of the memory system. Includes knowledge, skills, and experiences.

This model has since been updated ([FIGURE 8.3](#)) with important newer concepts, including *working memory* and *automatic processing*.

FIGURE 8.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.3 A modified three-stage processing model of memory

Atkinson and Shiffrin’s classic three-step model helps us to think about how memories are processed, but today’s researchers recognize other ways long-term memories form. For example, some information slips into long-term memory via a “back door,” without our consciously attending to it (*automatic processing*). And so much active processing occurs in the short-term memory stage that many now prefer the term *working memory*.

WORKING MEMORY Alan Baddeley and others (Baddeley, 2002; Barrouillet et al., 2011; Engle, 2002) extended Atkinson and Shiffrin’s initial view of short-term memory as a small, brief storage space for recent thoughts and experiences. This stage is not just a temporary shelf for holding incoming information. It’s an active scratchpad where your brain actively processes information by making sense of new input and linking it with long-term memories. It also works in the opposite direction, by processing already stored information. Whether we hear “eye-scream” as *ice cream* or *I scream* depends on how the context and our experience guide our interpreting and encoding of the sounds. To focus on the active processing that takes place in this middle stage, psychologists use the term [working memory](#). Right now, you are using your working memory to link the information you’re reading with your previously stored information (Cowan, 2010, 2016; Kail & Hall, 2001).

working memory a newer understanding of short-term memory that adds conscious, active processing of incoming auditory and visual information, and of information retrieved from long-term memory.

For most of you, what you are reading enters working memory through vision. You might also repeat the information using auditory rehearsal. As you integrate these memory inputs with your existing long-term memory, your attention is focused. In Baddeley's (2002) model, a *central executive* handles this focused processing.

Without focused attention, information often fades. If you think you can look something up later, you attend to it less and forget it more quickly. In one experiment, people read and typed new bits of trivia they would later need, such as "An ostrich's eye is bigger than its brain." If they knew the information would be available online, they invested less energy and remembered it less well (Sparrow et al., 2011; Wegner & Ward, 2013). Online, out of mind.

RETRIEVAL PRACTICE

RP-3 How does the *working memory* concept update the classic Atkinson-Shiffrin three-stage information-processing model?

ANSWER: The newer idea of a *working memory* emphasizes the active processing that we now know takes place in Atkinson-Shiffrin's short-term memory stage. While the Atkinson-Shiffrin model viewed short-term memory as a temporary holding space, working memory plays a key role in processing new information and connecting it to previously stored information.

RP-4 What are two basic functions of working memory?

ANSWER: (1) Active processing of incoming visual and auditory information, and (2) focusing our spotlight of attention.

For a 14-minute explanation and demonstration of our memory systems, see the **Video: Models of Memory**.

Encoding Memories

Dual-Track Memory: Effortful Versus Automatic Processing

LOQ 8-3 How do explicit and implicit memories differ?

Atkinson and Shiffrin's model focused on how we process our [explicit memories](#)—the facts and experiences that we can consciously know and declare (thus, also called *declarative memories*). We encode explicit memories through conscious [effortful processing](#). But our mind has a second, unconscious track. Behind the scenes, other information skips the conscious encoding track and barges directly into storage. This [automatic processing](#), which happens without our awareness, produces [implicit memories](#) (also called *nondeclarative memories*).

explicit memory retention of facts and experiences that one can consciously know and “declare.” (Also called *declarative memory*.)

effortful processing encoding that requires attention and conscious effort.

automatic processing unconscious encoding of incidental information, such as space, time, and frequency, and of well-learned information, such as word meanings.

implicit memory retention of learned skills or classically conditioned associations independent of conscious recollection. (Also called *nondeclarative memory*.)

Our two-track mind, then, helps us encode, retain, and recall information through both effortful and automatic tracks. Let's begin by seeing how automatic processing assists the formation of implicit memories.

Automatic Processing and Implicit Memories

LOQ 8-4 What information do we process automatically?

Our implicit memories include *procedural* memory for automatic skills (such as how to ride a bike) and classically conditioned *associations* among stimuli. If attacked by a dog in childhood, years later you may, without recalling the conditioned association, automatically tense up as a dog approaches.

Without conscious effort you also automatically process information about

- *space*. While studying, you often encode the place where certain material appears; later, when you want to retrieve the information, you may visualize its location.
- *time*. While going about your day, you unintentionally note the sequence of its events. Later, realizing you've left your coat somewhere, the event sequence your brain automatically encoded will enable you to retrace your steps.
- *frequency*. You effortlessly keep track of how many times things happen, as when you realize, "This is the third time I've run into her today."

Our two-track mind engages in impressively efficient information processing. As one track automatically tucks away routine details, the other track is free to focus on conscious, effortful processing. Mental feats such as vision, thinking, and memory may seem to be single abilities, but they are not. Rather, we split information into different components for separate and simultaneous processing.

Effortful Processing and Explicit Memories

Automatic processing happens effortlessly. When you see words in your native language, perhaps on the side of a delivery truck, you can't help but read them and register their meaning. *Learning* to read wasn't automatic. You may recall working hard to pick out letters and connect them to certain sounds. But with experience and practice, your reading became automatic. Imagine now learning to read sentences in reverse:

.citamotua emoceb nac gnissecorp luftroffE

At first, this requires effort, but after enough practice, you would also

perform this task much more automatically. We develop many skills in this way: driving, texting, and speaking a new language.

SENSORY MEMORY

LOQ 8-5 How does sensory memory work?

Sensory memory (recall [Figure 8.3](#)) feeds our active working memory, recording momentary images of scenes or echoes of sounds. How much of this page could you sense and recall with less exposure than a lightning flash? In one experiment, people viewed three rows of three letters each, for only one-twentieth of a second ([FIGURE 8.4](#)). After the nine letters disappeared, they could recall only about half of them.

K	Z	R
Q	B	T
S	G	N

FIGURE 8.4 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 8.4 Total recall—briefly

When George Sperling (1960) flashed a group of letters similar to this for one-twentieth of a second, people could recall only about half the letters. But when signaled to recall a particular row immediately after the letters had disappeared, they could do so with near-perfect accuracy.

Was it because they had insufficient time to glimpse them? *No*. People actually *could* see and recall all the letters, but only momentarily. Rather than ask them to recall all nine letters at once, researcher George Sperling sounded a high, medium, or low tone immediately *after* flashing the nine letters. This tone directed participants to report only the letters of the top, middle, or bottom row, respectively. Now they rarely missed a letter, showing that all nine letters were momentarily available for recall.

Sperling's experiment demonstrated [iconic memory](#), a fleeting sensory memory of visual stimuli. For a few tenths of a second, our eyes register a photographic or picture-image memory of a scene, and we can recall any part

of it in amazing detail. But delaying the tone signal by more than half a second caused the image to fade and memory to suffer. We also have an impeccable, though fleeting, memory for auditory stimuli, called **echoic memory** (Cowan, 1988; Lu et al., 1992). Picture yourself being distracted by a text message while you sit in class. If your mildly irked professor tests you by asking, “What did I just say?” you can recover the last few words from your mind’s echo chamber. Auditory echoes tend to linger for 3 or 4 seconds.

iconic memory a momentary sensory memory of visual stimuli; a photographic or picture-image memory lasting no more than a few tenths of a second.

echoic memory a momentary sensory memory of auditory stimuli; if attention is elsewhere, sounds and words can still be recalled within 3 or 4 seconds.

SHORT-TERM MEMORY CAPACITY

LOQ 8-6 What is our short-term memory capacity?

Recall that short-term memory refers to what we can briefly retain. The related idea of working memory also includes our active processing, as our brain makes sense of incoming information and links it with stored memories. What are the limits of what we can hold in this middle, short-term stage?

George Miller (1956) proposed that we can store about seven pieces of information (give or take two) in short-term memory. Miller’s magical number seven is psychology’s contribution to the list of magical sevens—the seven wonders of the world, the seven seas, the seven deadly sins, the seven colors of the rainbow, the seven musical scale notes, the seven days of the week—seven magical sevens.

After Miller’s 2012 death, his daughter recalled his best moment of golf: “He made the one and only hole-in-one of his life at the age of 77, on the seventh green . . . with a seven iron. He loved that” (quoted by Vitello, 2012).

Other researchers have confirmed that we can, if nothing distracts us, recall about seven digits. But the number varies by task; we tend to remember about six letters and only about five words (Baddeley et al., 1975; Cowan, 2015). And how quickly do our short-term memories disappear? To find out, Lloyd Peterson and Margaret Peterson (1959) asked people to remember three-consonant groups, such as *CHJ*. To prevent rehearsal, the researchers asked them, for example, to start at 100 and count aloud backward by threes. After 3 seconds, people recalled the letters only about half the time; after 12 seconds, they seldom recalled them at all ([FIGURE 8.5](#)). Without the active processing that we now understand to be a part of our working memory, short-term memories have a limited life.

FIGURE 8.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Peterson & Peterson, 1959

FIGURE 8.5 Short-term memory decay

Unless rehearsed, verbal information may be quickly forgotten.

Working memory capacity varies, depending on age and other factors. Compared with children and older adults, young adults have a greater working memory capacity. Having a large working memory capacity—the ability to juggle multiple items while processing information—tends to aid information retention after sleeping and creative problem solving (De Dreu et

al., 2012; Fenn & Hambrick, 2012; Wiley & Jarosz, 2012). But whatever our age, we do better and more efficient work when focused, without distractions, on one task at a time. *The bottom line*: It's probably a bad idea to try to watch TV, text your friends, and write a psychology paper all at the same time (Willingham, 2010)!

Unlike short-term memory capacity, working memory capacity appears to reflect intelligence level (Cowan, 2008; Shelton et al., 2010). Imagine seeing a letter of the alphabet, then a simple question, then another letter, followed by another question, and so on. In such experiments, those who could juggle the most mental balls—who could remember the most letters despite the interruptions—tended in everyday life to exhibit high intelligence and an ability to maintain their focus (Kane et al., 2007; Unsworth & Engle, 2007). When beeped to report in at various times, they were less likely than others to report that their mind was wandering.

For a review of memory stages and a test of your own short-term memory capacity, visit **Psych-Sim 6: Short-Term Memory**.

RETRIEVAL PRACTICE

RP-5 What is the difference between *automatic* and *effortful* processing, and what are some examples of each?

ANSWER: *Automatic* processing occurs unconsciously (automatically) for such things as the sequence and frequency of a day's events, and reading and comprehending words in our own language(s). *Effortful* processing requires attention and awareness and happens, for example, when we work hard to learn new material in class, or new lines for a play.

RP-6 At which of Atkinson-Shiffrin's three memory stages would *iconic* and *echoic* memory occur?

ANSWER: sensory memory

EFFORTFUL PROCESSING STRATEGIES

LOQ 8-7 What are some effortful processing strategies that can

help us remember new information?

Several effortful processing strategies can boost our ability to form new memories. Later, when we try to retrieve a memory, these strategies can make the difference between success and failure.

Chunking Glance for a few seconds at the first set of letters (row 1) in [FIGURE 8.6](#), then look away and try to reproduce what you saw. Impossible, yes? But you can easily reproduce set 2, which is no less complex. Similarly, you will probably remember sets 4 and 6 more easily than the same elements in sets 3 and 5. As this demonstrates, **chunking** information—organizing items into familiar, manageable units—enables us to recall it more easily. Try remembering 43 individual numbers and letters. It would be impossible, unless chunked into, say, seven meaningful chunks, such as “Try remembering 43 individual numbers and letters.” ☺

1.	M	U	<	S	R	W	F
2.	W	G	V	S	R	M	T

3.	VRESLI	UEGBN	GSORNW	CDOUL	LWLE	NTOD	WTO
4.	SILVER	BEGUN	WRONGS	CLOUD	WELL	DONT	TWO

5.	SILVER	BEGUN	WRONGS	CLOUD	DONT	TWO	
	HALF	MAKE	WELL	HAS	A		
	EVERY	IS	RIGHT	A	DONE	LINING	

6.	WELL	BEGUN	IS	HALF	DONE		
	EVERY	CLOUD	HAS	A	SILVER	LINING	
	TWO	WRONGS	DONT	MAKE	A	RIGHT

FIGURE 8.6 Chunking effects

Organizing information into meaningful units, such as letters, words, and phrases, helps us recall it more easily (Hintzman, 1978).

chunking organizing items into familiar, manageable units; often occurs automatically.

Chunking usually occurs so naturally that we take it for granted. If you are a native English speaker, you can reproduce perfectly the 150 or so line segments that make up the words in the three phrases of set 6 in [Figure 8.6](#). It would astonish someone unfamiliar with the language. We [DM and ND], who do not speak Chinese, are similarly awed by a Chinese reader's ability to glance at [FIGURE 8.7](#) and then reproduce all the strokes. Even the most committed sports fan may be amazed by a varsity basketball player's recall of all the players' positions after a 4-second peek at a basketball play (Allard & Burnett, 1985). We all remember information best when we can organize it into personally meaningful arrangements.

FIGURE 8.7 An example of chunking—for those who read Chinese

After looking at these characters, can you reproduce them exactly? If so, you can read Chinese.

Mnemonics To help encode lengthy passages and speeches, ancient Greek scholars and orators developed [mnemonics](#). Many of these memory aids use

vivid imagery, because we are particularly good at remembering mental pictures. We more easily remember concrete, visualizable words than we do abstract words (Akpınar & Berger, 2015). (When we quiz you later, which three of these words—*bicycle*, *void*, *cigarette*, *inherent*, *fire*, *process*—will you most likely recall?) If you still recall the rock-throwing rioter sentence, it is probably not only because of the meaning you encoded but also because the sentence painted a mental image.

mnemonics [nih-MON-iks] memory aids, especially those techniques that use vivid imagery and organizational devices.

Memory whizzes understand the power of such systems. Star performers in the World Memory Championships do not usually have exceptional intelligence, but rather are superior at using mnemonic strategies (Maguire et al., 2003b). Frustrated by his ordinary memory, science writer Joshua Foer wanted to see how much he could improve it. After a year of intense practice, he won the U.S. Memory Championship by memorizing a pack of 52 playing cards in under two minutes. How did Foer do it? He added vivid new details to memories of a familiar place—his childhood home. Each card, presented in any order, could then match up with the clear picture in his head. As the test subject of his own wild memory experiment, he learned that “you don’t have to be memorizing packs of playing cards to benefit from a little bit of insight into how your mind works” (Foer, 2011a,b).

When combined, chunking and mnemonic techniques can be great memory aids for unfamiliar material. Want to remember the colors of the rainbow in order of wavelength? Think of the mnemonic ROY G. BIV (*red, orange, yellow, green, blue, indigo, violet*). Need to recall the names of North America’s five Great Lakes? Just remember HOMES (*Huron, Ontario, Michigan, Erie, Superior*). In each case, we chunk information into a more familiar form by creating a word (called an *acronym*) from the first letters of the to-be-remembered items.

Hierarchies When people develop expertise in an area, they process information not only in chunks but also in *hierarchies* composed of a few broad concepts divided and subdivided into narrower concepts and facts. ([Figure 8.11](#) ahead provides a hierarchy of our automatic and effortful

memory processing systems.) Organizing knowledge in hierarchies helps us retrieve information efficiently, as Gordon Bower and his colleagues (1969) demonstrated by presenting words either randomly or grouped into categories. When the words were grouped, recall was two to three times better. Such results show the benefits of organizing what you study—of giving special attention to chapter outlines and headings, and, in this text, to numbered Learning Objective Questions. Taking lecture and text notes in outline format—a type of hierarchical organization—may also prove helpful.

DISTRIBUTED PRACTICE We retain information better when our encoding is distributed over time. Experiments have consistently revealed the benefits of this [spacing effect](#) (Cepeda et al., 2006; Soderstrom et al., 2016). *Massed practice* (cramming) can produce speedy short-term learning and a feeling of confidence. But to paraphrase early memory researcher Hermann Ebbinghaus (1885), those who learn quickly also forget quickly. *Distributed practice* produces better long-term recall. After you’ve studied long enough to master the material, further study at that time becomes inefficient. Better to spend that extra reviewing time later—a day later if you need to remember something 10 days hence, or a month later if you need to remember something 6 months hence (Cepeda et al., 2008). The spacing effect is one of psychology’s most reliable findings, and it extends to motor skills and online game performance, too (Stafford & Dewar, 2014). Memory researcher Henry Roediger (2013) sums it up: “Hundreds of studies have shown that distributed practice leads to more durable learning.”

spacing effect the tendency for distributed study or practice to yield better long-term retention than is achieved through massed study or practice.

“The mind is slow in unlearning what it has been long in learning.”

Roman philosopher Seneca (4 b.c.e.–65 c.e.)

One effective way to distribute practice is *repeated* self-testing, a phenomenon that researchers Roediger and Jeffrey Karpicke (2006) have called the [testing effect](#). Testing does more than assess learning and memory:

It improves them (Brown et al., 2014; Pan et al., 2015; Trumbo et al., 2016). Testing also protects our memory from the harmful effects of stress, which usually impairs memory retrieval (Smith et al., 2016). In this text, the Retrieval Practice questions and Review sections, including the Master the Material questions, offer opportunities to improve learning and memory. Better to practice retrieval (as any exam will demand) than to merely reread material (which may lull you into a false sense of mastery). Roediger (2013) explains, “Two techniques that students frequently report using for studying—highlighting (or underlining) text and rereading text—[have been found] ineffective.” Happily, “retrieval practice (or testing) is a powerful and general strategy for learning.” As another memory expert explained, “What we recall becomes more recallable” (Bjork, 2011). No wonder daily quizzing improves introductory psychology students’ course performance (Batsell et al., 2017; Pennebaker et al., 2013).

testing effect enhanced memory after retrieving, rather than simply rereading, information. Also sometimes referred to as a *retrieval practice effect* or *test-enhanced learning*.

W. H. Freeman & Worth Publishers

Making things memorable

For suggestions on how to apply the *testing effect* to your own learning, watch this 5-minute animation: tinyurl.com/HowToRemember.

The point to remember: Spaced study and self-assessment beat cramming and rereading. Practice may not make perfect, but smart practice—occasional rehearsal with self-testing—makes for lasting memories.

LEVELS OF PROCESSING

LOQ 8-8 What are the levels of processing, and how do they affect encoding?

Memory researchers have discovered that we process verbal information at different levels, and that depth of processing affects our long-term retention. **Shallow processing** encodes on an elementary level, such as a word's letters or, at a more intermediate level, a word's sound. Thus we may type *there* when we mean *their*, *write* when we mean *right*, and *two* when we mean *too*. **Deep processing** encodes *semantically*, based on the meaning of the words. The deeper (more meaningful) the processing, the better our retention.

shallow processing encoding on a basic level, based on the structure or appearance of words.

deep processing encoding semantically, based on the meaning of the words; tends to yield the best retention.

In one classic experiment, researchers Fergus Craik and Endel Tulving (1975) flashed words at viewers. Then they asked them questions that would elicit different levels of processing. To experience the task yourself, rapidly answer the following sample questions:

Sample Questions to Elicit Different Levels of Processing	Word Flashed	Yes	No
<i>Most shallow:</i> Is the word in capital letters?	CHAIR	_____	_____
<i>Shallow:</i> Does the word rhyme with train?	brain	_____	_____
<i>Deep:</i> Would the word fit in this sentence? The girl put the _____ on the table.	doll	_____	_____

Which type of processing would best prepare you to recognize the words at a later time? In Craik and Tulving's experiment, the deeper, semantic processing triggered by the third question yielded a much better memory than

did the shallower processing elicited by the second question or the very shallow processing elicited by the first question (which was especially ineffective).

MAKING MATERIAL PERSONALLY MEANINGFUL If new information is neither meaningful nor related to our experience, we have trouble processing it. Imagine being asked to remember the following recorded passage:

The procedure is actually quite simple. First you arrange things into different groups. Of course, one pile may be sufficient depending on how much there is to do. . . . After the procedure is completed, one arranges the materials into different groups again. Then they can be put into their appropriate places. Eventually they will be used once more and the whole cycle will then have to be repeated. However, that is part of life.

When some students heard the paragraph you have just read, without a meaningful context, they remembered little of it (Bransford & Johnson, 1972). When others were told the paragraph described washing clothes (something meaningful), they remembered much more of it—as you probably could now after rereading it.

Can you repeat the sentence about the rioter that we gave you at this chapter's beginning (“The angry rioter threw . . .”)? Perhaps, like those in an experiment by William Brewer (1977), you recalled the sentence by the meaning you encoded when you read it (for example, “The angry rioter threw the rock *through* the window”) and not as it was written (“The angry rioter threw the rock *at* the window”). Referring to such mental mismatches, some researchers have likened our minds to theater directors who, given a raw script, imagine the finished stage production (Bower & Morrow, 1990). Asked later what we heard or read, we recall not the literal text but *what we encoded*. Thus, studying for an exam, you may remember your lecture notes rather than the lecture itself.

We can avoid some of these mismatches by rephrasing what we see and hear into meaningful terms. From his experiments on himself, Ebbinghaus estimated that, compared with learning nonsense material, learning meaningful material required one-tenth the effort. As memory researcher Wayne Wickelgren (1977, [p. 346](#)) noted, “The time you spend thinking about material you are reading and relating it to previously stored material is about the most useful thing you can do in learning any new subject matter.”

Psychologist-actor team Helga Noice and Tony Noice (2006) have described how actors inject meaning into the daunting task of learning “all those lines.” They do it by first coming to understand the flow of meaning: “One actor divided a half-page of dialogue into three [intentions]: ‘to flatter,’ ‘to draw him out,’ and ‘to allay his fears.’” With this meaningful sequence in mind, the actor more easily remembers the lines.

Most people excel at remembering personally relevant information. Asked how well certain adjectives describe someone else, we often forget them; asked how well the adjectives describe us, we often remember them. This tendency, called the *self-reference effect*, is especially strong in members of individualist Western cultures (Symons & Johnson, 1997; Wagar & Cohen, 2003). In contrast, members of collectivist Eastern cultures tend to remember self-relevant and family-relevant information equally well (Sparks et al., 2016). Knowing this, you can understand why some people retain information deemed “relevant to me,” whereas others also remember information relevant to “my family.”

The point to remember: The amount remembered depends both on the time spent learning and on your making it meaningful for deep processing.

RETRIEVAL PRACTICE

RP-7 Which strategies are better for long-term retention: cramming and rereading material, or spreading out learning over time and repeatedly testing yourself?

ANSWER: Although cramming and rereading may lead to short-term gains in knowledge, distributed practice and repeated self-testing will result in the greatest long-term retention.

RP-8 If you try to make the material you are learning personally meaningful, are you processing at a shallow or a deep level? Which level leads to greater retention?

ANSWER: Making material personally meaningful involves processing at a deep level, because you are processing *semantically*—based on the meaning of the words. Deep processing leads to greater retention.

REVIEW Studying and Encoding Memories

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

A psychologist who asks you to write down as many objects as you can remember having seen a few minutes earlier is testing your _____.

The psychological terms for taking in information, retaining it, and later getting it back out are _____, _____, and _____.

The concept of working memory

- clarifies the idea of short-term memory by focusing on the active processing that occurs in this stage.
- splits short-term memory into two substages—sensory memory and iconic

memory.

- c. splits short-term memory into two types: implicit and explicit memory.
- d. clarifies the idea of short-term memory by focusing on space, time, and frequency.

Sensory memory may be visual (_____ memory) or auditory (_____ memory).

Our short-term memory for new information is limited to about _____ items.

Memory aids that use visual imagery or other organizational devices (such as acronyms) are called _____.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Storing and Retrieving Memories

Memory Storage

LOQ 8-9 What is the capacity of long-term memory? Are our long-term memories processed and stored in specific locations?

In Arthur Conan Doyle's *A Study in Scarlet*, Sherlock Holmes offers a popular theory of memory capacity:

I consider that a man's brain originally is like a little empty attic, and you have to stock it with such furniture as you choose. . . . It is a mistake to think that that little room has elastic walls and can distend to any extent. Depend upon it, there comes a time when for every addition of knowledge you forget something that you knew before.

Contrary to Holmes' "memory model," our brain is *not* like an attic, which once filled can store more items only if we discard old ones. Our capacity for storing long-term memories is essentially limitless. One research team, after studying the brain's neural connections, estimated its storage capacity as "in the same ballpark as the World Wide Web" (Sejnowski, 2016).

Retaining Information in the Brain

I [DM] marveled at my aging mother-in-law, a retired pianist and organist. At age 88, her blind eyes could no longer read music. But let her sit at a keyboard and she would flawlessly play any of hundreds of hymns, including ones she had not thought of for 20 years. Where did her brain store those thousands of sequenced notes?

For a time, some surgeons and memory researchers marveled at patients' apparently vivid memories triggered by brain stimulation during surgery. Did this prove that our whole past, not just well-practiced music, is "in there," in complete detail, just waiting to be relived? On closer analysis, the seeming

flashbacks appeared to have been invented, not a vivid reliving of long-forgotten experiences (Loftus & Loftus, 1980). In a further demonstration that memories do not reside in single, specific spots, psychologist Karl Lashley (1950) trained rats to find their way out of a maze, then surgically removed pieces of their brain's cortex and retested their memory. No matter which small brain section he removed, the rats retained at least a partial memory of how to navigate the maze. Memories *are* brain-based, but the brain distributes the components of a memory across a network of locations. These specific locations include some of the circuitry involved in the original experience: Some brain cells that fire when we experience something fire again when we recall it (Miller, 2012a; Miller et al., 2013).

The point to remember: Despite the brain's vast storage capacity, we do not store information as libraries store their books, in single, precise locations. Instead, brain networks encode, store, and retrieve the information that forms our complex memories.

“Our memories are flexible and superimposable, a panoramic blackboard with an endless supply of chalk and erasers.”

Elizabeth Loftus and Katherine Ketcham, *The Myth of Repressed Memory*,
1994

EXPLICIT MEMORY SYSTEM: THE FRONTAL LOBES AND HIPPOCAMPUS

LOQ 8-10 What roles do the frontal lobes and hippocampus play in memory processing?

Explicit, conscious memories are either [semantic](#) (facts and general knowledge) or [episodic](#) (experienced events). The network that processes and stores new explicit memories for these facts and episodes includes your frontal lobes and hippocampus. When you summon up a mental encore of a past experience, many brain regions send input to your frontal lobes for working memory processing (de Chastelaine et al., 2016; Michalka et al., 2015). The left and right frontal lobes process different types of memories. Recalling a password and holding it in working memory, for example, would activate the left frontal lobe. Calling up a visual party scene would more likely activate the right frontal lobe.

semantic memory explicit memory of facts and general knowledge; one of our two conscious memory systems (the other is *episodic memory*).

episodic memory explicit memory of personally experienced events; one of our two conscious memory systems (the other is *semantic memory*).

Cognitive neuroscientists have found that the **hippocampus**, a temporal-lobe neural center located in the limbic system, can be likened to a “save” button for explicit memories (**FIGURE 8.8**). Brain scans reveal activity in the hippocampus and nearby brain networks as people form explicit memories of names, images, and events (Squire & Wixted, 2011; Wang et al., 2014).

hippocampus a neural center located in the limbic system; helps process explicit (conscious) memories—of facts and events—for storage.

FIGURE 8.8 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Roger Harris/Science Source

FIGURE 8.8 The hippocampus

Explicit memories for facts and episodes are processed in the hippocampus (orange structures) and fed to other brain regions for storage.

Damage to this structure therefore disrupts the formation and recall of

explicit memories. If their hippocampus is severed, chickadees and other birds will continue to cache food in hundreds of places, but later be unable to find them (Kamil & Cheng, 2001; Sherry & Vaccarino, 1989). With left-hippocampus damage, people have trouble remembering verbal information, but they have no trouble recalling visual designs and locations. With right-hippocampus damage, the problem is reversed (Schacter, 1996).

Subregions of the hippocampus also serve different functions. One part is active as people and mice learn social information (Okuyama et al., 2016; Zeineh et al., 2003). Another part is active as memory champions engage in spatial mnemonics (Maguire et al., 2003a). The rear area, which processes spatial memory, grows bigger as London cabbies navigate the city's complicated maze of streets (Woollett & Maguire, 2011).

Tim Zurowski/
All Canada Photos/
Getty Images

Hippocampus hero

Among animals, one contender for champion memorist would be a mere birdbrain—the Clark's Nutcracker—which during winter and spring can locate up to 6000 caches of pine seed it had previously buried (Shettleworth, 1993).

Memories are not permanently stored in the hippocampus. Instead, this structure seems to act as a loading dock where the brain registers and temporarily holds the elements of a to-be-remembered episode—its smell, feel, sound, and location. Then, like older files shifted to a basement

storeroom, memories migrate for storage elsewhere. This storage process is called [memory consolidation](#). Removing a rat's hippocampus 3 hours after it learns the location of some tasty new food disrupts this process and prevents long-term memory formation; removal 48 hours later does not (Tse et al., 2007).

memory consolidation the neural storage of a long-term memory.

Sleep supports memory consolidation. During deep sleep, the hippocampus processes memories for later retrieval. After a training experience, the greater one's heart rate efficiency and hippocampus activity during sleep, the better the next day's memory will be (Peigneux et al., 2004; Whitehurst et al., 2016). Researchers have watched the hippocampus and brain cortex displaying simultaneous activity rhythms during sleep, as if they were having a dialogue (Euston et al., 2007; Mehta, 2007). They suspect that the brain is replaying the day's experiences as it transfers them to the cortex for long-term storage (Squire & Zola-Morgan, 1991). When our learning is distributed over days rather than crammed into a single day, we experience more sleep-induced memory consolidation. And that helps explain the spacing effect.

Mark Parisi/offthemark.com

IMPLICIT MEMORY SYSTEM: THE CEREBELLUM AND BASAL GANGLIA

LOQ 8-11 What roles do the cerebellum and basal ganglia play in memory processing?

Your hippocampus and frontal lobes are processing sites for your *explicit* memories. But you could lose those areas and still, thanks to automatic processing, lay down *implicit* memories for skills and newly conditioned associations. Joseph LeDoux (1996) recounted the story of a brain-damaged patient whose amnesia left her unable to recognize her physician as, each day, he shook her hand and introduced himself. One day, she yanked her hand back, for the physician had pricked her with a tack in his palm. The next time he returned to introduce himself she refused to shake his hand but couldn't explain why. Having been classically conditioned, she just wouldn't do it. Implicitly, she felt what she could not explain.

The *cerebellum* plays a key role in forming and storing the implicit memories created by classical conditioning. With a damaged cerebellum, people cannot develop certain conditioned reflexes, such as associating a tone with an impending puff of air—and thus do not blink in anticipation of the puff (Daum & Schugens, 1996; Green & Woodruff-Pak, 2000). Implicit memory formation needs the cerebellum.

The *basal ganglia*, deep brain structures involved in motor movement, facilitate formation of our procedural memories for skills (Mishkin, 1982; Mishkin et al., 1997). The basal ganglia receive input from the cortex but do not return the favor of sending information back to the cortex for conscious awareness of procedural learning. If you have learned how to ride a bike, thank your basal ganglia.

Our implicit memory system, enabled by these more ancient brain areas, helps explain why the reactions and skills we learned during infancy reach far into our future. Yet as adults, our *conscious* memory of our first four years is largely blank, an experience called *infantile amnesia*. In one study, events children experienced and discussed with their mothers at age 3 were 60 percent remembered at age 7 but only 34 percent remembered at age 9 (Bauer et al., 2007). Two influences contribute to infantile amnesia: First, we index much of our explicit memory with a command of language that young children do not possess. Second, the hippocampus is one of the last brain structures to mature, and as it does, more gets retained (Akers et al., 2014).

RETRIEVAL PRACTICE

RP-9 Which parts of the brain are important for *implicit* memory processing, and which parts play a key role in *explicit* memory processing?

ANSWER: The cerebellum and basal ganglia are important for *implicit* memory processing, and the frontal lobes and hippocampus are key to *explicit* memory formation.

RP-10 Your friend has experienced brain damage in an accident. He can remember how to tie his shoes but has a hard time remembering anything you tell him during a conversation. How can implicit versus explicit information processing explain what's going on here?

ANSWER: Our *explicit* conscious memories of facts and episodes differ from our *implicit* memories of skills (such as tying shoelaces) and classically conditioned responses. The parts of the brain involved in explicit memory processing (the frontal lobes and hippocampus) may have sustained

damage in the accident, while the parts involved in implicit memory processing (the cerebellum and basal ganglia) appear to have escaped harm.

THE AMYGDALA, EMOTIONS, AND MEMORY

LOQ 8-12 How do emotions affect our memory processing?

Our emotions trigger stress hormones that influence memory formation. When we are excited or stressed, these hormones make more glucose energy available to fuel brain activity, signaling the brain that something important is happening. Moreover, stress hormones focus memory. Stress provokes the *amygdala* (two limbic system, emotion-processing clusters) to initiate a memory trace that boosts activity in the brain's memory-forming areas (Buchanan, 2007; Kensinger, 2007) ([FIGURE 8.9](#)). It's as if the amygdala says, "Brain, encode this moment for future reference!" The result? Emotional arousal can sear certain events into the brain, while disrupting memory for irrelevant events (Brewin et al., 2007; McGaugh, 2015).

FIGURE 8.9 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 8.9 Review key memory structures in the brain

Frontal lobes and *hippocampus*: explicit memory formation

Cerebellum and *basal ganglia*: implicit memory formation

Amygdala: emotion-related memory formation

Significantly stressful events can form almost unforgettable memories. After a traumatic experience—a school shooting, a house fire, a rape—vivid recollections of the horrific event may intrude again and again. It is as if they were burned in: “Stronger emotional experiences make for stronger, more reliable memories,” noted James McGaugh (1994, 2003). Such experiences even strengthen recall for relevant, immediately preceding events (Dunsmoor et al., 2015; Jobson & Cheraghi, 2016). This makes adaptive sense: Memory serves to predict the future and to alert us to potential dangers. Emotional events produce tunnel vision memory. They focus our attention and recall on high priority information, and reduce our recall of irrelevant details (Mather & Sutherland, 2012). Whatever rivets our attention gets well recalled, at the expense of the surrounding context.

Emotion-triggered hormonal changes help explain why we long remember exciting or shocking events, such as our first kiss or our whereabouts when learning of a loved one’s death. In a 2006 Pew survey, 95 percent of American adults said they could recall exactly where they were or what they were doing when they first heard the news of the 9/11 terrorist attacks. This perceived clarity of memories of surprising, significant events leads some psychologists to call them [flashbulb memories](#).

flashbulb memory a clear memory of an emotionally significant moment or event.

The people who experienced a 1989 San Francisco earthquake had perfect recall, a year and a half later, of where they had been and what they were doing (verified by their recorded thoughts within a day or two of the quake). Others’ memories for the circumstances under which they merely *heard* about the quake were more prone to errors (Neisser et al., 1991; Palmer et al., 1991).

Which is more important—your experiences or your memories of them?

Our flashbulb memories are noteworthy for their vividness and our

confidence in them. But as we relive, rehearse, and discuss them, even these memories may come to err. With time, some errors crept into people's 9/11 recollections (compared with their earlier reports taken right after 9/11).

Mostly, however, people's memories of 9/11 remained consistent over the next two to three years (Conway et al., 2009; Hirst et al., 2009).

Dramatic experiences remain clear in our memory in part because we rehearse them (Hirst & Phelps, 2016). We think about them and describe them to others. Memories of personally important experiences also endure (Storm & Jobe, 2012; Talarico & Moore, 2012). Compared with non-Catholics, devout Catholics recalled better the resignation of Pope Benedict XVI (Curci et al., 2015). Ditto for baseball fans' memories of their team's championship games (Breslin & Safer, 2011). When their team won, fans enjoyed recalling and recounting the victory, leading to longer-lasting memories.

For an 8-minute examination of emotion's effect on memory, see the **Video: The Role of Emotion**.

Synaptic Changes

LOQ 8-13 How do changes at the synapse level affect our memory processing?

As you read this chapter and think and learn about memory processes, your brain is changing. Given increased activity in particular pathways, neural interconnections are forming and strengthening.

The quest to understand the physical basis of memory—how information becomes embedded in brain matter—has sparked study of the synaptic meeting places where neurons communicate with one another via their neurotransmitter messengers. Eric Kandel and James Schwartz (1982) observed synaptic changes during learning in the neurons of the California sea slug, *Aplysia*, a simple animal with a mere 20,000 or so unusually large and accessible nerve cells. A sea slug can be classically conditioned (with electric shock) to reflexively withdraw its gills when squirted with water, much as a soldier traumatized by combat might jump at the sound of a firecracker. When learning occurs, Kandel and Schwartz discovered, the slug releases more of the neurotransmitter *serotonin* into certain neurons. These

cells' synapses then become more efficient at transmitting signals. Experience and learning can increase—even double—the number of synapses, even in slugs (Kandel, 2012).

© Donna Ikenberry/Art Directors & TRIP/Alamy

Aplysia

The California sea slug, which neuroscientist Eric Kandel studied for 45 years, has increased our understanding of the neural basis of learning and memory.

In experiments with people, rapidly stimulating certain memory-circuit connections has increased their sensitivity for hours or even weeks to come. The sending neuron now needs less prompting to release its neurotransmitter, and more connections exist between neurons. This increased efficiency of potential neural firing, called [long-term potentiation \(LTP\)](#), provides a neural basis for learning and remembering associations (Lynch, 2002; Whitlock et al., 2006) ([FIGURE 8.10](#)). Several lines of evidence confirm that LTP is a physical basis for memory:

- Drugs that block LTP interfere with learning (Lynch & Staubli, 1991).
- Drugs that mimic what happens during learning increase LTP (Harward et al., 2016).
- Rats given a drug that enhanced LTP learned a maze with half the usual number of mistakes (Service, 1994).

FIGURE 8.10 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
From N. Toni et al, *Nature*, 402, Nov. 25, 1999. Dominique Muller

FIGURE 8.10 Doubled receptor sites

An electron microscope image (a) shows just one receptor site (gray) reaching toward a sending neuron before long-term potentiation. Image (b) shows that, after LTP, the receptor sites have doubled. This means the receiving neuron has increased sensitivity for detecting the presence of the neurotransmitter molecules that may be released by the sending neuron. (From Toni et al., 1999.)

long-term potentiation (LTP) an increase in a cell's firing potential after brief, rapid stimulation; a neural basis for learning and memory.

After LTP has occurred, passing an electric current through the brain won't disrupt old memories. But the current will wipe out very recent memories. Such is the experience both of laboratory animals and of severely depressed people given *electroconvulsive therapy (ECT)*. A blow to the head can do the same. Football players and boxers momentarily knocked unconscious typically have no memory of events just before the knockout (Yarnell & Lynch, 1970). Their working memory had no time to consolidate the information into long-term memory before the lights went out.

Recently, I [DM] did a little test of memory consolidation. While on an operating table for a basketball-related tendon repair, I was given a face mask and soon could smell the anesthesia gas. “So how much longer will I be with you?” I asked the anesthesiologist. My last moment of memory was her answer: “About 10 seconds.” My brain spent that 10 seconds consolidating a memory for her words, but could not tuck any further memory away before I was out cold.

Some memory-biology explorers have helped found companies that are

competing to develop memory-altering drugs. The target market for memory-boosting drugs includes millions of people with Alzheimer's disease, millions more with *mild cognitive impairment* that often becomes Alzheimer's, and countless millions who would love to turn back the clock on age-related memory decline. Meanwhile, one safe and free memory enhancer is already available: effective study techniques followed by adequate *sleep*!

One approach to improving memory focuses on drugs that boost the LTP-enhancing neurotransmitter *glutamate* (Lynch et al., 2011). Another approach involves developing drugs that boost production of CREB, a protein that also enhances the LTP process (Fields, 2005). Boosting CREB production might trigger increased production of other proteins that help reshape synapses and transfer short-term memories into long-term memories.

Some of us may wish for memory-*blocking* drugs that, when taken after a traumatic experience, might blunt intrusive memories (Adler, 2012; Kearns et al., 2012). In one experiment, victims of car accidents, rapes, and other traumas received, for 10 days following their horrific event, either one such drug, propranolol, or a placebo. When tested three months later, half the placebo group but none of the drug-treated group showed signs of stress disorder (Pitman & Delahanty, 2005; Pitman et al., 2002).

FIGURE 8.11 summarizes the brain's two-track memory processing and storage system for implicit (automatic) and explicit (effortful) memories. *The bottom line:* Learn something and you change your brain a little.

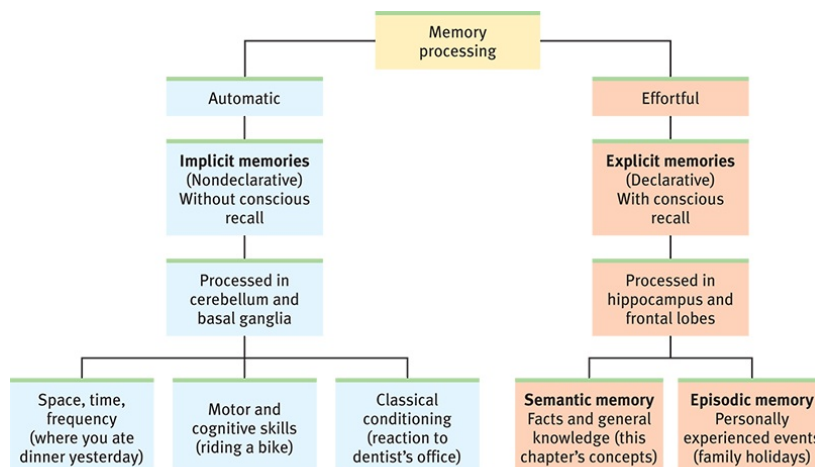

FIGURE 8.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.11 Our two memory systems

RETRIEVAL PRACTICE

RP-11 Which brain area responds to stress hormones by helping to create stronger memories?

ANSWER: the amygdala

RP-12 Increased efficiency at the synapses is evidence of the neural basis of learning and memory. This is called

_____ - _____ .

ANSWER: long-term potentiation.

Memory Retrieval

After the magic of brain encoding and storage, we still have the daunting task of retrieving the information. What triggers retrieval?

Retrieval Cues

LOQ 8-14 How do external cues, internal emotions, and order of appearance influence memory retrieval?

Imagine a spider suspended in the middle of her web, held up by the many strands extending outward from her in all directions to different points. If you were to trace a pathway to the spider, you would first need to create a path from one of these anchor points and then follow the strand down into the web.

The process of retrieving a memory follows a similar principle, because memories are held in storage by a web of associations, each piece of information interconnected with others. When you encode into memory a target piece of information, such as the name of the person sitting next to you in class, you associate with it other bits of information about your surroundings, mood, seating position, and so on. These bits can serve as *retrieval cues* that you can later use to access the information. The more retrieval cues you have, the better your chances of finding a route to the suspended memory. To remember to do something (say, to write a note

tomorrow), one effective strategy is to mentally associate the act with a cue (perhaps a pen left in the middle of your desk) (Rogers & Milkman, 2016).

“Memory is not like a container that gradually fills up; it is more like a tree growing hooks onto which memories are hung.”

Peter Russell, *The Brain Book*, 1979

The best retrieval cues come from associations we form at the time we encode a memory—smells, tastes, and sights that can evoke our memory of the associated person or event. To call up visual cues when trying to recall something, we may mentally place ourselves in the original context. After losing his sight, British scholar John Hull (1990, [p. 174](#)) described his difficulty recalling such details:

I knew I had been somewhere, and had done particular things with certain people, but where? I could not put the conversations . . . into a context. There was no background, no features against which to identify the place. Normally, the memories of people you have spoken to during the day are stored in frames which include the background.

For an 8-minute synopsis of how we access what's stored in our brain, see the **Video: Memory Retrieval**.

PRIMING Often our associations are activated without our awareness. Philosopher-psychologist William James referred to this process, which we call [priming](#), as the “wakening of associations.” After seeing or hearing the word *rabbit*, we are later more likely to spell the spoken word *hair/hare* as *h-a-r-e*, even if we don’t recall seeing or hearing *rabbit* ([FIGURE 8.12](#)).

priming the activation, often unconsciously, of particular associations in memory.

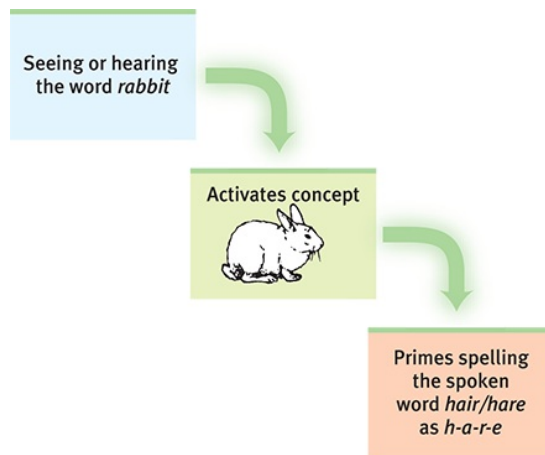

FIGURE 8.12 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 8.12 Priming

Associations unconsciously activate related associations (Bower, 1986).

Priming is often “memoryless memory”—invisible memory, without your conscious awareness. If, walking down a hallway, you see a poster of a missing child, you will then unconsciously be primed to interpret an ambiguous adult-child interaction as a possible kidnapping (James, 1986). Although you no longer have the poster in mind, it predisposes your interpretation. Meeting someone who reminds us of a person we’ve previously met can awaken our associated feelings about that earlier person, which may transfer into the new context (Andersen & Saribay, 2005; Lewicki, 1985).

Priming can influence behaviors as well (Herring et al., 2013). Adults and children primed with money-related words and materials were less likely to help another person when asked (Gasiorowska et al., 2016; Vohs et al., 2006). In such cases, money may prime our materialism and self-interest rather than the social norms that encourage us to help (Ariely, 2009).

CONTEXT-DEPENDENT MEMORY Have you noticed? Putting yourself back in the context where you experienced something can prime your memory retrieval. Remembering, in many ways, depends on our environment (Palmer, 1989). When you visit your childhood home or neighborhood, old memories surface. When scuba divers listened to a word list in two different settings (either 10 feet underwater or sitting on the beach), they recalled more words if tested in the same place (Godden & Baddeley, 1975).

Ask a friend three rapid-fire questions: (a) What color is snow? (b) What color are clouds? (c) What do cows drink? If your friend answers “milk” to the third question, you have demonstrated priming.

By contrast, experiencing something outside the usual setting can be confusing. Have you ever run into a former teacher in an unusual place, such as at the store or park? Perhaps you recognized the person but struggled to figure out who it was and how you were acquainted. The **encoding specificity principle** helps us understand how cues *specific* to an event or person will most effectively trigger that memory. In new settings, you may not have the memory cues needed for speedy face recognition. Our memories are *context-dependent*, and are affected by the cues we have associated with that context.

encoding specificity principle the idea that cues and contexts specific to a particular memory will be most effective in helping us recall it.

In several experiments, Carolyn Rovee-Collier (1993) found that a familiar context could activate memories even in 3-month-olds. After infants learned that kicking would make a crib mobile move via a connecting ribbon from the ankle, the infants kicked more when tested again in the same crib than when in a different context.

STATE-DEPENDENT MEMORY Closely related to context-dependent memory is *state-dependent memory*. What we learn in one state—be it drunk or sober—may be more easily recalled when we are again in that state. What people learn when drunk they don’t recall well in any state (alcohol disrupts memory storage). But they recall it slightly better when again drunk. Someone who hides money when drunk may forget the location until drunk again.

Moods also provide an example of memory’s state dependence. Emotions that accompany good or bad events become retrieval cues (Gaddy & Ingram, 2014). Thus, our memories are somewhat **mood congruent**. If you’ve had a bad evening—your date never showed, your Toledo Mud Hens hat disappeared, your TV went out 10 minutes before the end of a show—your gloomy mood may facilitate recalling other bad times. Being depressed sours

memories by priming negative associations, which we then use to explain our current mood. In many experiments, people put in a buoyant mood—whether under hypnosis or just by the day’s events (a World Cup soccer victory for German participants in one study)—recall the world through rose-colored glasses (DeSteno et al., 2000; Forgas et al., 1984; Schwarz et al., 1987). They recall their behaviors as competent and effective, other people benevolent, happy events more frequent.

mood-congruent memory the tendency to recall experiences that are consistent with one’s current good or bad mood.

"I can't remember what we're arguing about, either. Let's keep yelling, and maybe it will come back to us."

The New Yorker Collection, 2005 David Sipress
from cartoonbank.com. All Rights Reserved.

Have you ever noticed that your mood influences your perceptions of your parents? In one study, adolescents’ ratings of parental warmth in one week gave little clue to how they would rate their parents six weeks later (Bornstein et al., 1991). When teens were down, their parents seemed cruel; as their mood brightened, their parents morphed from devils into angels. We may nod our heads knowingly. Yet, in a good or bad mood, we persist in attributing to reality our own changing judgments, memories, and interpretations. In a bad mood, we may read someone’s look as a glare and feel even worse. In a good mood, we may encode the same look as interest

and feel even better. Moods magnify.

Mood effects on retrieval help explain why our moods persist. When happy, we recall happy events and therefore see the world as a happy place, which helps prolong our good mood. When depressed, we recall sad events, which darkens our interpretations of current events. For those of us predisposed to depression, this process can help maintain a vicious, dark cycle.

“When a feeling was there, they felt as if it would never go; when it was gone, they felt as if it had never been; when it returned, they felt as if it had never gone.”

George MacDonald, *What's Mine's Mine*, 1886

SERIAL POSITION EFFECT Another memory-retrieval quirk, the [serial position effect](#), explains why we may have large holes in our memory of a list of recent events. Imagine it's your first day in a new job, and your manager is introducing co-workers. As you meet each person, you silently repeat everyone's name, starting from the beginning. As the last person smiles and turns away, you feel confident you'll be able to greet your new co-workers by name the next day.

serial position effect our tendency to recall best the last (*recency effect*) and first (*primacy effect*) items in a list.

Don't count on it. Because you have spent more time rehearsing the earlier names than the later ones, those are the names you'll probably recall more easily the next day. In experiments, when people viewed a list of items (words, names, dates, even experienced odors) and immediately tried to recall them in any order, they fell prey to the serial position effect (Reed, 2000). They briefly recalled the last items especially quickly and well (a *recency effect*), perhaps because those last items were still in working memory. But after a delay, when their attention was elsewhere, their recall was best for the first items (a *primacy effect*; see [FIGURE 8.13](#)).

FIGURE 8.13 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Vincenzo Pinto/AFP/Getty Images

FIGURE 8.13 The serial position effect

Immediately after Pope Francis made his way through this receiving line of special guests, he would probably have recalled the names of the last few people best (*recency effect*). But later he may have been able to recall the first few people best (*primacy effect*).

RETRIEVAL PRACTICE

RP-13 What is priming?

ANSWER: *Priming* is the activation (often without our awareness) of associations. Seeing a gun, for example, might temporarily predispose someone to interpret an ambiguous face as threatening or to recall a boss as nasty.

RP-14 When we are tested immediately after viewing a list of words, we tend to recall the first and last items best, which is known as the _____ effect.

ANSWER: serial position

For a simulated experiment showing the probability of recalling a specific item from a list, engage online with **Concept Practice: The Serial Position Effect**.

REVIEW Storing and Retrieving Memories

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

LOQ 8-9 [What is the capacity of long-term memory? Are our long-term memories processed and stored in specific locations?](#)

LOQ 8-10 [What roles do the frontal lobes and hippocampus play in memory processing?](#)

LOQ 8-11 [What roles do the cerebellum and basal ganglia play in memory processing?](#)

LOQ 8-12 [How do emotions affect our memory processing?](#)

LOQ 8-13 [How do changes at the synapse level affect our memory processing?](#)

LOQ 8-14 [How do external cues, internal emotions, and order of appearance influence memory retrieval?](#)

TERMS AND CONCEPTS TO REMEMBER

Test yourself on these terms by trying to compose the definition before checking your answers.

[semantic memory](#), p. 307

[episodic memory](#), p. 307

[hippocampus](#), p. 307

[memory consolidation](#), p. 308

[flashbulb memory](#), p. 308

[priming](#), p. 312

[encoding specificity principle](#), p. 313

[mood-congruent memory](#), p. 313

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The hippocampus seems to function as a

- a. temporary processing site for explicit memories.
- b. temporary processing site for implicit memories.
- c. permanent storage area for emotion-based memories.
- d. permanent storage area for iconic and echoic memories.

Hippocampus damage typically leaves people unable to learn new facts or recall recent events. However, they may be able to learn new skills, such as riding a bicycle, which is an _____ (explicit/implicit) memory.

Long-term potentiation (LTP) refers to

- a. emotion-triggered hormonal changes.
- b. the role of the hippocampus in processing explicit memories.
- c. an increase in a cell's firing potential.
- d. aging people's potential for learning.

Specific odors, visual images, emotions, or other associations that help us access a memory are examples of _____.

When you feel sad, why might it help to look at pictures that reawaken some of your best memories?

When tested immediately after viewing a list of words, people tend to recall the first and last items more readily than those in the middle.

When retested after a delay, they are most likely to recall

- a. the first items on the list.
- b. the first and last items on the list.
- c. a few items at random.
- d. the last items on the list.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  LearningCurve to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Forgetting, Memory Construction, and Improving Memory

Forgetting

LOQ 8-15 Why do we forget?

Amid all the applause for memory—all the efforts to understand it, all the books on how to improve it—have any voices been heard in praise of forgetting? William James (1890, p. 680) was such a voice: “If we remembered everything, we should on most occasions be as ill off as if we remembered nothing.” To discard the clutter of useless or out-of-date information—where we parked the car yesterday, our old phone number, restaurant orders already cooked and served—is surely a blessing (Nørby, 2015). The Russian memory whiz S, whom we met at the beginning of this chapter, was haunted by his junk heap of memories. They dominated his consciousness. He had difficulty thinking abstractly—generalizing, organizing, evaluating. After reading a story, he could recite it but would struggle to summarize its gist.

“Amnesia seeps into the crevices of our brains, and amnesia heals.”

Joyce Carol Oates, “Words Fail, Memory Blurs, Life Wins,” 2001

Dan Tuffs/Getty Images

The woman who can't forget

Jill Price, with writer Bart Davis, told her story in a 2008 published memoir. Price remembers every day of her life since age 14 with detailed clarity, including both the joys and the hurts. Researchers have identified enlarged brain areas in people with super memory (Ally et al., 2013; LePort et al., 2012).

A more recent case of a life overtaken by memory is Jill Price, whose experience has been studied by a University of California at Irvine research team, along with several dozen other cases of “highly superior autobiographical memory” (McGaugh & LePort, 2014; Parker et al., 2006). Price compares her memory to “a running movie that never stops. It’s like a split screen. I’ll be talking to someone and seeing something else. . . . Whenever I see a date flash on the television (or anywhere for that matter) I automatically go back to that day and remember where I was, what I was doing, what day it fell on, and on and on and on and on. It is nonstop, uncontrollable, and totally exhausting.” Jill, and others like her, are prone to letting their minds get absorbed by information that, once it enters memory

storage, never leaves (Patihis, 2016). A good memory is helpful, but so is the ability to forget. If a memory-enhancing pill ever becomes available, it had better not be *too* effective.

More often, however, our unpredictable memory dismays and frustrates us. Memories are quirky. My [DM's] own memory can easily call up such episodes as that wonderful first kiss with the woman I love, or trivial facts like the air mileage from London to Detroit. Then it abandons me when I discover I have failed to encode, store, or retrieve a student's name or where I left my sunglasses. See how you do with remembering this sentence when we ask you about it later: *The fish attacked the swimmer*.

As we process information, we sift, change, or lose most of it ([FIGURE 8.14](#)).

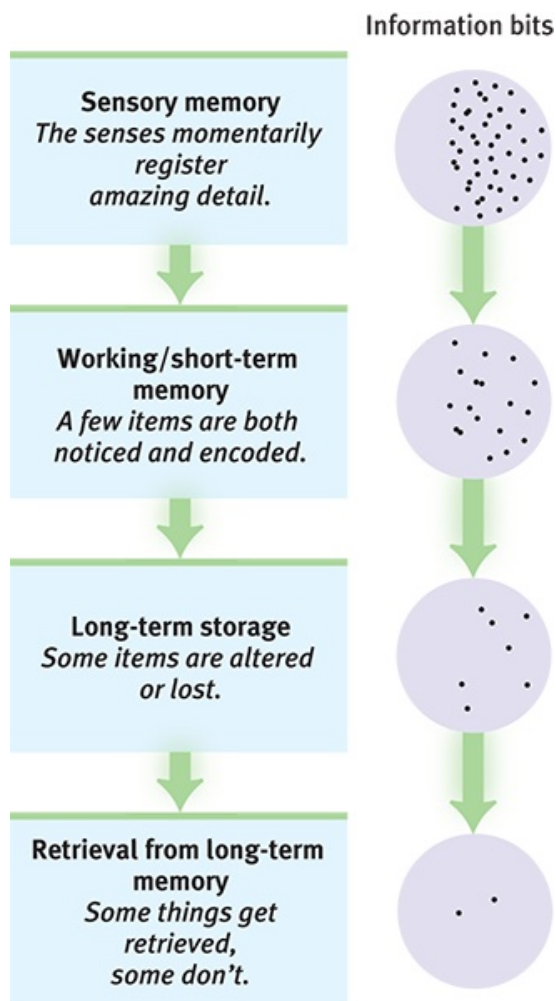

FIGURE 8.14 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 8.14 When do we forget?

Forgetting can occur at any memory stage. When we process information, we filter, alter, or lose much of it.

Forgetting and the Two-Track Mind

For some, memory loss is severe and permanent. Consider Henry Molaison (or H. M., as he was known until his 2008 death). Surgeons removed much of his hippocampus in order to stop severe seizures. This resulted “in severe disconnection of the remaining hippocampus” from the rest of the brain (Annese et al., 2014). For his remaining 55 years, Molaison was unable to form new conscious memories. He was, as before his surgery, intelligent and did daily crossword puzzles. Yet, reported neuroscientist Suzanne Corkin (2005, 2013), “I’ve known H. M. since 1962, and he still doesn’t know who I am.” For about half a minute he could keep something in mind, enough to carry on a conversation. When distracted, he would lose what was just said or what had just occurred. Without the neural tissue for turning new information into long-term memories, he never could name the current president of the United States (Ogden, 2012).

Molaison suffered from [anterograde amnesia](#)—he could recall his past, but he could not form new memories. (Those who cannot recall their past—the old information stored in long-term memory—suffer from [retrograde amnesia](#).)

anterograde amnesia an inability to form new memories.

retrograde amnesia an inability to retrieve information from one's past.

Neurologist Oliver Sacks (1985, pp. 26–27) described another patient, Jimmie, who had anterograde amnesia resulting from brain damage. Jimmie had no memories—thus, no sense of elapsed time—beyond his injury in 1945.

When Jimmie gave his age as 19, Sacks set a mirror before him: “Look in the mirror and tell me what you see. Is that a 19-year-old looking out from the mirror?”

Jimmie turned ashen, gripped the chair, cursed, then became frantic: “What’s going on? What’s happened to me? Is this a nightmare? Am I crazy? Is this a joke?” When his attention was diverted to some children playing baseball, his panic ended, the dreadful mirror forgotten.

Sacks showed Jimmie a photo from *National Geographic*. “What is this?” he asked.

“It’s the Moon,” Jimmie replied.

“No, it’s not,” Sacks answered. “It’s a picture of the Earth taken from the Moon.”

“Doc, you’re kidding! Someone would’ve had to get a camera up there!”

“Naturally.”

“Hell! You’re joking—how the hell would you do that?” Jimmie’s wonder was that of a bright young man from the 1940s, amazed by his travel back to the future.

“Oh, is that today?”

© The New Yorker Collection, 2007 Robert Leighton from cartoonbank.com. All Rights Reserved.

For a helpful tutorial animation about this type of research method, see the **Video: Case Studies**.

Careful testing of these unique people reveals something even stranger: Although incapable of recalling new facts or anything they have done recently, Molaison, Jimmie, and others with similar conditions can learn

nonverbal tasks. Shown hard-to-find figures in pictures (in the *Where's Waldo?* series), they can quickly spot them again later. They can find their way to the bathroom, though without being able to tell you where it is. They can learn to read mirror-image writing or do a jigsaw puzzle, and they have even learned complicated job skills (Schacter, 1992, 1996; Xu & Corkin, 2001). They can be classically conditioned. However, *they do all these things with no awareness of having learned them*. “Well, this is strange,” Molaison said, after demonstrating his nondeclarative memory of skillful mirror tracing. “I thought that would be difficult. But it seems as though I’ve done it quite well” (Shapin, 2013).

Molaison and Jimmie lost their ability to form new explicit memories, but their automatic processing ability remained intact. Like Alzheimer’s patients, whose *explicit* memories for new people and events are lost, they could form new *implicit* memories (Lustig & Buckner, 2004). These patients can learn *how* to do something, but they will have no conscious recall of learning their new skill. Such sad cases confirm that we have two distinct memory systems, controlled by different parts of the brain.

For most of us, forgetting is a less drastic process. Let’s consider some of the reasons we forget.

“Waiter, I’d like to order, unless I’ve eaten, in which case bring me the check.”

© The New Yorker Collection, 1992, Robert Mankoff
from cartoonbank.com. All Rights Reserved.

Encoding Failure

Much of what we sense we never notice, and what we fail to encode, we will never remember ([FIGURE 8.15](#)). The English novelist and critic C. S. Lewis

(1967, [p. 107](#)) described the enormity of what we never encode:

FIGURE 8.15 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.15 Forgetting as encoding failure

We cannot remember what we have not encoded.

[We are] bombarded every second by sensations, emotions, thoughts . . . nine-tenths of which [we] must simply ignore. The past [is] a roaring cataract of billions upon billions of such moments: Any one of them too complex to grasp in its entirety, and the aggregate beyond all imagination. . . . At every tick of the clock, in every inhabited part of the world, an unimaginable richness and variety of ‘history’ falls off the world into total oblivion.

Age can affect encoding efficiency. The brain areas that jump into action when young adults encode new information are less responsive in older adults. This slower encoding helps explain age-related memory decline (Grady et al., 1995).

But no matter how young we are, we selectively attend to few of the myriad sights and sounds continually bombarding us. Consider: You have surely seen the Apple logo thousands of times. Can you draw it? In one study, only 1 of 85 UCLA students (including 52 Apple users) could do so accurately (Blake et al., 2015). Most people also struggle to recall details of other familiar objects, such as their country’s coins (Nickerson & Adams, 1979; Richardson, 1993). Without encoding effort, many potential memories never form.

Storage Decay

Even after encoding something well, we sometimes later forget it. To study the durability of stored memories, Ebbinghaus (1885) learned more lists of nonsense syllables and measured how much he retained when relearning each list, from 20 minutes to 30 days later. The result, confirmed by later experiments, was his famous forgetting curve: *The course of forgetting is initially rapid, then levels off with time* ([FIGURE 8.16](#); Wixted & Ebbesen,

1991). Harry Bahrick (1984) found a similar forgetting curve for Spanish vocabulary learned in school. Compared with those just completing a high school or college Spanish course, people 3 years out of school had forgotten much of what they had learned ([FIGURE 8.17](#)). However, what people remembered then, they still remembered 25 and more years later. Their forgetting had leveled off.

FIGURE 8.16 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Ebbinghaus, 1885.

FIGURE 8.16 Ebbinghaus' forgetting curve

After learning lists of nonsense syllables, such as YOX and JIH, Ebbinghaus studied how much he retained up to 30 days later. He found that memory for novel information fades quickly, then levels out.

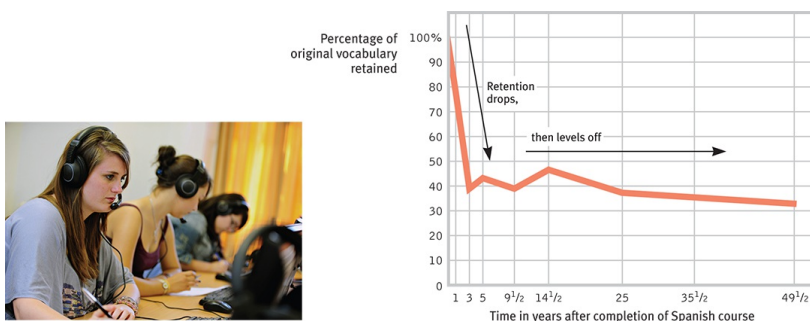

FIGURE 8.17 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Jon Parker Lee/Alamy; Data from Bahrick, 1984.

FIGURE 8.17 The forgetting curve for Spanish learned in school

Compared with people just completing a Spanish course, those 3 years out of the course remembered much less (on a vocabulary recognition test). Compared with the 3-year group, however, those who studied Spanish even longer ago did not forget much more.

One explanation for these forgetting curves is a gradual fading of the

physical memory trace. Cognitive neuroscientists are getting closer to solving the mystery of the physical storage of memory and are increasing our understanding of how memory storage could decay. Like books you can't find in your campus library, memories may be inaccessible for many reasons. Some were never acquired (not encoded). Others were discarded (stored memories decay). And others are out of reach because we can't retrieve them.

Retrieval Failure

Often, forgetting is not memories faded but memories unretrieved. We store in long-term memory what's important to us or what we've rehearsed. But sometimes important events defy our attempts to access them ([FIGURE 8.18](#)). How frustrating when a name lies poised on the tip of our tongue, just beyond reach. Given retrieval cues (*"It begins with an M"*), we may easily retrieve the elusive memory. Retrieval problems contribute to the occasional memory failures of older adults, who more frequently are frustrated by tip-of-the-tongue forgetting (Abrams, 2008; Salthouse & Mandell, 2013).

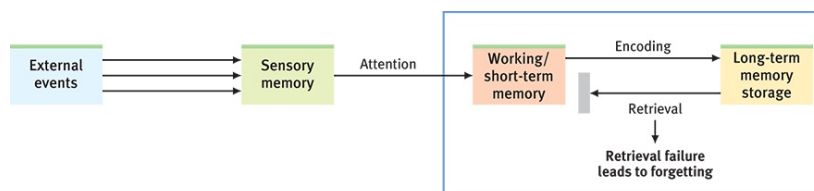

FIGURE 8.18 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.18 Retrieval failure

Sometimes even stored information cannot be accessed, which leads to forgetting.

Deaf persons fluent in sign language experience a parallel “tip of the fingers” phenomenon (Thompson et al., 2005).

Do you recall the gist of the sentence about the attacked swimmer that we asked you to remember? If not, does the word *shark* serve as a retrieval cue? Experiments show that *shark* (likely what you visualized) more readily retrieves the image you stored than does the sentence's actual word, *fish* (Anderson et al., 1976). (The sentence was “*The fish attacked the swimmer.*”)

But retrieval problems occasionally stem from interference and even from motivated forgetting.

INTERFERENCE As you collect more and more information, your mental attic never fills, but it does get cluttered. Your brain tries to keep things tidy: As you, for example, use a new password, it weakens your memory of competing old passwords (Wimber et al., 2015). But sometimes the clutter wins, and new and old learning collide. **Proactive** (*forward-acting*) **interference** occurs when prior learning disrupts your recall of new information. If you buy a new combination lock, your well-rehearsed old combination may interfere with your retrieval of the new one.

proactive interference the forward-acting disruptive effect of older learning on the recall of *new* information.

Retroactive (*backward-acting*) **interference** occurs when new learning disrupts recall of old information. If someone sings new lyrics to the tune of an old song, you may have trouble remembering the original words. It is rather like a second stone tossed in a pond, disrupting the waves rippling out from the first.

retroactive interference the backward-acting disruptive effect of newer learning on the recall of *old* information.

Information presented in the hour before sleep suffers less retroactive interference because the opportunity for interfering events is minimized (Mercer, 2015). Researchers John Jenkins and Karl Dallenbach (1924) first discovered this in a now-classic experiment. Day after day, two people each learned some nonsense syllables, then tried to recall them after up to eight hours of being awake or asleep at night. As **FIGURE 8.19** shows, forgetting occurred more rapidly after being awake and involved with other activities. The investigators surmised that “forgetting is not so much a matter of the decay of old impressions and associations as it is a matter of interference, inhibition, or obliteration of the old by the new” (1924, [p. 612](#)).

FIGURE 8.19 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Jenkins & Dallenbach, 1924.

FIGURE 8.19 Retroactive interference

More forgetting occurred when a person stayed awake and experienced other new material.

Dave Coverly/Speed Bump

The hour before sleep is a good time to commit information to memory (Scullin & McDaniel, 2010), though information presented in the *seconds* just before sleep is seldom remembered (Wyatt & Bootzin, 1994). If you're considering learning *while* sleeping, forget it. We have little memory for information played aloud in the room during sleep, although the ears do register it (Wood et al., 1992).

Old and new learning do not always compete with each other, of course. Previously learned information (Latin) often facilitates our learning of new

information (French). This phenomenon is called *positive transfer*.

To experience a demonstration and explanation of interference effects on memory, visit **Psych-Sim 6: Forgetting**.

MOTIVATED FORGETTING To remember our past is often to revise it. Years ago, the huge cookie jar in my [DM's] kitchen was jammed with freshly baked chocolate chip cookies. Still more were cooling across racks on the counter. Twenty-four hours later, not a crumb was left. Who had taken them? During that time, my wife, three children, and I were the only people in the house. So while memories were still fresh, I conducted a little memory test. Andy admitted wolfing down as many as 20. Peter thought he had eaten 15. Laura guessed she had stuffed her then-6-year-old body with 15 cookies. My wife, Carol, recalled eating 6, and I remembered consuming 15 and taking 18 more to the office. We sheepishly accepted responsibility for 89 cookies. Still, we had not come close; there had been 160.

Peter Johansky/Photolibrary/
Getty Images

Why do our memories fail us? This happens in part because memory is an “unreliable, self-serving historian” (Tavris & Aronson, 2007, [p. 6](#)). Consider one study, in which researchers told some participants about the benefits of frequent toothbrushing. Those individuals then recalled (more than others did) having frequently brushed their teeth in the preceding two weeks (Ross et al., 1981).

So why were my family and I so far off in our estimates of the cookies we had eaten? Was it an *encoding* problem? (Did we just not notice what we had eaten?) Was it a storage problem? (Might our memories of cookies, like

Ebbinghaus' memory of nonsense syllables, have melted away almost as fast as the cookies themselves?) Or was the information still intact but not *retrievable* because it would be embarrassing to remember?¹

Sigmund Freud might have argued that our memory systems self-censored this information. He proposed that we **repress** painful or unacceptable memories to protect our self-concept and to minimize anxiety. But the repressed memory lingers, he believed, and can be retrieved by some later cue or during therapy. Repression was central to Freud's psychoanalytic theory of personality and remains a popular idea. One Norwegian study found that educated people tend to believe in repressed memories more than do those with less formal education (Magnussen et al., 2006). Indeed, an American study revealed that 81 percent of university students, and 60 to 90 percent of therapists (depending on their perspective), believe that "traumatic memories are often repressed" (Patihis et al., 2014a,b). However, increasing numbers of memory researchers think repression rarely, if ever, occurs. People succeed in forgetting unwanted neutral information (yesterday's parking place), but it's harder to forget emotional events (Payne & Corrigan, 2007). Thus, we may have intrusive memories of the very same traumatic experiences we would most like to forget.

repression in psychoanalytic theory, the basic defense mechanism that banishes from consciousness anxiety-arousing thoughts, feelings, and memories.

RETRIEVAL PRACTICE

RP-15 What are three ways we forget, and how does each of these happen?

ANSWER: (1) *Encoding failure*: Unattended information never entered our memory system. (2) *Storage decay*: Information fades from our memory. (3) *Retrieval failure*: We cannot access stored information accurately, sometimes due to interference or motivated forgetting.

RP-16 You will experience less _____ (proactive/retroactive)

interference if you learn new material in the hour before sleep than you will if you learn it before turning to another subject.

ANSWER: retroactive.

RP-17 Freud believed that we _____ unacceptable memories to minimize anxiety.

ANSWER: repress.

Stringer/European Pressphoto Agency/Lages/PORTUGAL/Newscom

Do people vividly remember—or repress—traumatic experiences?

Imagine yourself several hours into Flight AT236 from Toronto to Lisbon. A fractured fuel line begins leaking. Soon the engines go silent and primary electrical power is lost. In the eerie silence, the pilots instruct you and the other terrified passengers to don life jackets, and, when hearing the countdown to ocean impact, to assume a brace position. After minutes of descent the pilot declares above the passengers' screams and prayers, "About to go into the water." Death awaits.

Memory Construction Errors

LOQ 8-16 How do misinformation, imagination, and source amnesia

influence our memory construction? How do we decide whether a memory is real or false?

Nearly two-thirds of Americans agree: “Human memory works like a video camera, accurately recording the events we see and hear so that we can review and inspect them later” (Simons & Chabris, 2011). Actually, memory is not so precise. Like scientists who infer a dinosaur’s appearance from its remains, we infer our past from stored information plus what we later imagined, expected, saw, and heard. We don’t just retrieve memories, we reweave them.

David Sipress

Our memories are like Wikipedia pages, capable of continuous revision. When we “replay” a memory, we often replace the original with a slightly modified version, rather like what happens in the telephone game, as a whispered message gets progressively altered when passed from person to person (Hardt et al., 2010). (Memory researchers call this [reconsolidation](#).) So, in a sense, said Joseph LeDoux (2009), “your memory is only as good as your last memory. The fewer times you use it, the more pristine it is.” This means that, to some degree, “all memory is false” (Bernstein & Loftus, 2009b).

reconsolidation a process in which previously stored memories, when retrieved, are potentially altered before being stored again.

Despite knowing all this, I [DM] recently rewrote my own past. It happened at an international conference, where memory researcher Elizabeth Loftus (2012) was demonstrating how memory works. Loftus showed us a handful of individual faces that we were later to identify, as if in a police lineup. Then she showed us some pairs of faces, one face we had seen earlier and one we had not, and asked us to identify the one we had seen. But one pair she had slipped in included *two* new faces, one of which was rather *like* a face we had seen earlier. Most of us understandably but wrongly identified this face as one we had previously seen. To climax the demonstration, when she showed us the originally seen face and the previously chosen wrong face, most of us picked the wrong face! As a result of our memory reconsolidation, we—an audience of psychologists who should have known better—had replaced the original memory with a false memory.

Clinical researchers have experimented with memory reconsolidation. People recalled a traumatic or negative experience and then had the reconsolidation of that memory disrupted, with a drug or brief, painless electroconvulsive shock (Kroes et al., 2014; Lonergan et al., 2013). Someday it might become possible to erase your memory of a specific traumatic experience—by reactivating your memory and then disrupting its storage in this way. Would you wish for this? If brutally assaulted, would you welcome having your memory of the attack and its associated fears deleted?

Misinformation and Imagination Effects

In more than 200 experiments involving more than 20,000 people, Loftus has shown how eyewitnesses reconstruct their memories after a crime or accident. In one important study, two groups of people watched a film clip of a traffic accident and then answered questions about what they had seen (Loftus & Palmer, 1974). Those asked, “About how fast were the cars going when they *smashed* into each other?” gave higher speed estimates than those asked, “About how fast were the cars going when they *hit* each other?” A week later, when asked whether they recalled seeing any broken glass, people who had heard *smashed* were more than twice as likely to report seeing glass fragments ([FIGURE 8.20](#)). In fact, the clip showed no broken glass.

FIGURE 8.20 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 8.20 Memory construction

In this experiment, people viewed a film clip of a car accident. Those who later were asked a leading question recalled a more serious accident than they had witnessed (Loftus & Palmer, 1974).

In many follow-up experiments around the world, others have witnessed an event, received or not received misleading information about it, and then taken a memory test. The repeated result is a **misinformation effect**: When exposed to misleading information, we tend to misremember (Loftus et al., 1992). A yield sign becomes a stop sign, hammers become screwdrivers, Coke cans become peanut cans, breakfast cereal becomes eggs, and a clean-shaven man morphs into a man with a mustache.

misinformation effect occurs when misleading information has corrupted one's memory of an event.

“Memory is insubstantial. Things keep replacing it. Your batch of snapshots will both fix and ruin your memory. . . . You can’t remember anything from your trip except the wretched collection of snapshots.”

Annie Dillard, “To Fashion a Text,” 1988

So powerful is the misinformation effect that it can influence later attitudes and behaviors (Bernstein & Loftus, 2009a). One experiment falsely suggested to some Dutch university students that, as children, they became ill after eating spoiled egg salad (Geraerts et al., 2008). After absorbing that suggestion, they were less likely to eat egg salad sandwiches, both immediately and four months later.

Even repeatedly *imagining* nonexistent actions and events can create false memories. In one study, Canadian university students were asked to recall two events from their past. One event actually happened; the other was a false event that involved committing a crime, such as assaulting someone with a weapon. Initially, none of the lawful students remembered breaking the law. But after repeated interviewing, 70 percent of students reported a detailed false memory of having committed the crime (Shaw & Porter, 2015).

Misinformation and imagination effects occur partly because visualizing something and actually perceiving it activate similar brain areas (Gonsalves et al., 2004). Imagined events also later seem more familiar, and familiar things seem more real. The more vividly we can imagine things, the more likely they are to become memories (Loftus, 2001; Porter et al., 2000).

Evan Agostini/Invision/AP

Was Alexander Hamilton a U.S. president?

Sometimes our mind tricks us into misremembering dates, places, and names. This often happens because we misuse familiar information. In one study, many people mistakenly recalled Alexander Hamilton—the subject of a popular Broadway musical whose face also appears on the U.S. \$10 bill—as a U.S. president (Roediger & DeSoto, 2016).

Digitally altered photos have also produced this *imagination inflation*. In experiments, researchers have altered photos from a family album to show some family members taking a hot air balloon ride. After viewing these photos (rather than photos showing just the balloon), children reported more false memories and indicated high confidence in those memories. When interviewed several days later, they reported even richer details of their false memories (Strange et al., 2008; Wade et al., 2002). Similarly, when *Slate* magazine readers in 2012 were shown a doctored photo of U.S. President

Barack Obama and Iranian President Mahmoud Ahmadinejad shaking hands, 26 percent recalled the event—despite it never having happened (Frenda et al., 2013).

Patrick Andrade/Polaris Images/Newscom

“Lying Brian”? Or a victim of false memory?

In 2015, *NBC Nightly News* anchor Brian Williams recounted a story about traveling in a military helicopter that was hit with a rocket-propelled grenade. But the event never happened as he described. The public branded him as a liar, leading his bosses to fire him. Several memory researchers had a different opinion. “I think a lot of people don’t appreciate the extent to which false memories can happen even when we are extremely confident in the memory,” noted psychologist Christopher Chabris (2015).

In British and Canadian university surveys, one-fourth of students have reported autobiographical memories that they later realized were not accurate (Foley, 2015; Mazzoni et al., 2010). I [DM] empathize. For decades, my cherished earliest memory was of my parents getting off the bus and walking to our house, bringing my baby brother home from the hospital. When, in middle age, I shared that memory with my father, he assured me they did *not* bring their newborn home on the Seattle Transit System. The human mind, it seems, comes with built-in Photoshopping software. The moral: Don’t believe everything you remember.

In the discussion of mnemonics, we gave you six words and told you

we would quiz you about them later. How many of these words can you now recall? Of these, how many are high-imagery words? How many are low-imagery?²

Source Amnesia

What is the frailest part of a memory? Its source. We may recognize someone but have no idea where we have seen the person. We may dream an event and later be unsure whether it really happened. We may misrecall how we learned about something (Henkel et al., 2000). Famed child psychologist Jean Piaget was startled as an adult to learn that a vivid, detailed memory from his childhood—a nursemaid’s thwarting his kidnapping—was utterly false. He apparently constructed the memory from repeatedly hearing the story (which his nursemaid, after undergoing a religious conversion, later confessed had never happened). In attributing his “memory” to his own experiences, rather than to his nursemaid’s stories, Piaget exhibited [source amnesia](#) (also called *source misattribution*). Misattribution is at the heart of many false memories. Authors, songwriters, and stand-up comedians sometimes suffer from it. They think an idea came from their own creative imagination, when in fact they are unintentionally plagiarizing something they earlier read or heard.

source amnesia faulty memory for how, when, or where information was learned or imagined. (Also called *source misattribution*.) Source amnesia, along with the misinformation effect, is at the heart of many false memories. (p. 322)

“It isn’t so astonishing, the number of things I can remember, as the number of things I can remember that aren’t so.”

Author Mark Twain (1835–1910)

Famous psychologists and artists aren’t the only ones to experience source amnesia. Preschoolers interacted with “Mr. Science,” who engaged them in activities such as blowing up a balloon with baking soda and vinegar (Poole & Lindsay, 1995, 2001). Three months later, on three successive days, their

parents read them a story describing some things the children had experienced with Mr. Science and some they had not. When a new interviewer asked what Mr. Science had done with them—“Did Mr. Science have a machine with ropes to pull?”—4 in 10 children spontaneously recalled him doing things that had happened only in the story.

Source amnesia also helps explain [déjà vu](#) (French for “already seen”). Two-thirds of us have experienced this fleeting, eerie sense that “I’ve been in this exact situation before.” The key to déjà vu seems to be familiarity with a stimulus without a clear idea of where we encountered it before (Brown & Marsh, 2009; Cleary, 2008). Normally, we experience a feeling of *familiarity* (thanks to temporal lobe processing) before we consciously remember details (thanks to hippocampus and frontal lobe processing). When these functions (and brain regions) are out of sync, we may experience a feeling of familiarity without conscious recall. Our amazing brains try to make sense of such an improbable situation, and we get an eerie feeling that we’re reliving some earlier part of our life. Our source amnesia forces us to do our best to make sense of an odd moment.

déjà vu that eerie sense that “I’ve experienced this before.” Cues from the current situation may unconsciously trigger retrieval of an earlier experience. (p. 322)

“Do you ever get that strange feeling of vujà dé? Not déjà vu; vujà dé. It’s the distinct sense that, somehow, something just happened that has never happened before. Nothing seems familiar. And then suddenly the feeling is gone. Vujà dé.”

Comedian George Carlin (1937–2008), in *Funny Times*, December 2001

Discerning True and False Memories

Since memory is reconstruction as well as reproduction, we can’t be sure whether a memory is real by how real it feels. Much as perceptual illusions may seem like real perceptions, unreal memories *feel* like real memories.

Because the misinformation effect and source amnesia happen outside our awareness, it is hard to separate false memories from real ones (Schooler et al., 1986). Perhaps you can recall describing a childhood experience to a friend and filling in memory gaps with reasonable guesses. We all do it. After more retellings, those guessed details—now absorbed into your memory—may feel as real as if you had actually observed them (Roediger et al., 1993). False memories, like fake diamonds, seem so real.

False memories can be persistent. Imagine that we were to read aloud a list of words such as *candy*, *sugar*, *honey*, and *taste*. Later, we ask you to recognize the presented words from a larger list. If you are at all like the people tested by Henry Roediger and Kathleen McDermott (1995), you would err three out of four times—by falsely remembering a nonpresented similar word, such as *sweet*. We more easily remember the gist than the words themselves.

Memory construction can help us understand why some people have been sent to prison for crimes they never committed. Of 337 people who were later proven not guilty by DNA testing, 71 percent had been convicted because of faulty eyewitness identification (Innocence Project, 2015; Smalarz & Wells, 2015). It explains why “hypnotically refreshed” memories of crimes so easily incorporate errors, some of which originate with the hypnotist’s leading questions (“*Did you hear loud noises?*”). It explains why dating partners who fell in love have *overestimated* their first impressions of one another (“*It was love at first sight*”), while those who broke up *underestimated* their earlier liking (“*We never really clicked*”) (McFarland & Ross, 1987). And it explains why people asked how they felt 10 years ago about marijuana or gender issues recalled attitudes closer to their current views than to the views they had actually reported a decade earlier (Markus, 1986). People tend to recall having always felt as they feel today (Mazzoni & Vannucci, 2007).

One research team interviewed 73 ninth-grade boys and then reinterviewed them 35 years later. When asked to recall how they had reported their attitudes, activities, and experiences, most men recalled their ninth-grade statements at a rate no better than chance. Only 1 in 3 now remembered receiving physical punishment, though as ninth-graders 82 percent had said they had (Offer et al., 2000). As George Vaillant (1977, [p. 197](#)) noted after following adult lives through time, “It is all too common for caterpillars to become butterflies and then to maintain that in their youth they had been little butterflies. Maturation makes liars of us all.” Memory

construction errors also seem to be at work in many “recovered” memories of childhood abuse. See Thinking Critically About: Can Memories of Childhood Sexual Abuse Be Repressed and Then Recovered?

Thinking Critically About: Can Memories of Childhood Sexual Abuse Be Repressed and Then Recovered?

Two Possible Tragedies:

1. People doubt childhood sexual abuse survivors who tell their secret.
2. **Innocent people are falsely accused**, as therapists prompt “recovered” memories of childhood sexual abuse:

LOQ 8-17 Why have reports of repressed and recovered memories been so hotly debated?

Well-intentioned therapist

Misinformation effect and source amnesia: Adult client may form image of threatening person.

With rehearsal (repeated therapy sessions), the image grows more vivid.

Client is stunned, angry, and ready to confront or sue the remembered abuser.

Accused person is equally stunned and vigorously denies the long-ago accusation.

Professional organizations (including the American Medical, American Psychological, and American Psychiatric Associations) are working to find sensible common ground to resolve psychology's “memory war”:¹

- **Childhood sexual abuse happens** and can leave its victims at risk for problems ranging from sexual dysfunction to depression.² But there is no “survivor syndrome”—no group of symptoms that lets us spot victims of sexual abuse.³
- **Injustice happens.** Innocent people have been falsely convicted. And guilty people have avoided punishment by casting doubt on their truth-telling accusers.
- **Forgetting happens.** Children abused when very young may not have understood the meaning of their experience or remember it. Forgetting long-ago good and bad events is an ordinary part of everyday life.
- **Recovered memories are common.** Cued by a remark or an experience, we may recover pleasant or unpleasant memories of long-forgotten events. But does the unconscious mind forcibly repress painful experiences, and can these experiences be recovered by therapist-aided techniques?⁴ Memories that surface naturally are more likely to be true.⁵
- **Memories of events before age 4 are unreliable.** Infantile amnesia results from not yet developed brain pathways. Most psychologists therefore doubt “recovered” memories of abuse during infancy.⁶ The older a child was when suffering sexual abuse, and the more severe the abuse, the more likely it is to be remembered.⁷
- **Memories “recovered” under hypnosis are especially unreliable.**
- **Memories, whether real or false, can be emotionally upsetting.** What was born of mere suggestion can become, like an actual event, a stinging memory that drives bodily stress.⁸

Psychologists question whether repression ever occurs. (See Chapter 14 for more on this concept—the cornerstone of Freud's theory and of so much popular psychology.)

Traumatic experiences (witnessing a loved one's murder, being terrorized by a hijacker or rapist, losing everything in a natural disaster)

→ TYPICALLY LEAD TO →

vivid, persistent, haunting memories⁹

The Royal College of Psychiatrists Working Group on Reported Recovered Memories of Child Sexual Abuse advised that “when memories are ‘recovered’ after long periods of amnesia, particularly when extraordinary means were used to secure the recovery of memory, there is a high probability that the memories are false.”¹⁰

Children's Eyewitness Recall

LOQ 8-18 How reliable are young children's eyewitness descriptions?

If memories can be sincere, yet sincerely wrong, how can jurors decide cases in which children's memories of sexual abuse are the only evidence? “It would be truly awful to ever lose sight of the enormity of child abuse,”

observed Stephen Ceci (1993). Yet Ceci and Maggie Bruck's (1993, 1995) studies of children's memories have made them aware of how easily children's memories can be molded. For example, they asked 3-year-olds to show on anatomically correct dolls where a pediatrician had touched them. Of the children who had not received genital examinations, 55 percent pointed to either genital or anal areas.

In other experiments, the researchers studied the effect of suggestive interviewing techniques (Bruck & Ceci, 1999, 2004). In one study, children chose a card from a deck of possible happenings, and an adult then read the card to them. For example, "Think real hard, and tell me if this ever happened to you. Can you remember going to the hospital with a mousetrap on your finger?" In interviews, the same adult repeatedly asked children to think about several real and fictitious events. After 10 weeks of this, a new adult asked the same question. The stunning result: 58 percent of preschoolers produced false (often vivid) stories regarding one or more events they had never experienced (Ceci et al., 1994). Here's one:

My brother Colin was trying to get Blowtorch [an action figure] from me, and I wouldn't let him take it from me, so he pushed me into the wood pile where the mousetrap was. And then my finger got caught in it. And then we went to the hospital, and my mommy, daddy, and Colin drove me there, to the hospital in our van, because it was far away. And the doctor put a bandage on this finger.

© Darren Matthews/Alamy

Given such detailed stories, professional psychologists who specialize in interviewing children could not reliably separate the real memories from the false ones. Nor could the children themselves. The above child, reminded that his parents had told him several times that the mousetrap incident never happened—that he had imagined it—protested, "But it really did happen. I

remember it!” Unfortunately, this type of error is common. In one analysis of eyewitness data from over 20,000 participants, children regularly identified innocent suspects as guilty (Fitzgerald & Price, 2015). “[The] research,” said Ceci (1993), “leads me to worry about the possibility of false allegations. It is not a tribute to one’s scientific integrity to walk down the middle of the road if the data are more to one side.”

Children can, however, be accurate eyewitnesses. When questioned about their experiences in neutral words they understood, children often accurately recalled what happened and who did it (Brewin & Andrews, 2016; Goodman, 2006). When interviewers used less suggestive, more effective techniques, even 4- to 5-year-old children produced more accurate recall (Holliday & Albon, 2004; Pipe et al., 2004). Children were especially accurate when they had not talked with involved adults prior to the interview and when their disclosure was made in a first interview with a neutral person who asked nonleading questions.

Consider how researchers have studied these issues by engaging online with **Immersive Learning: How Would You Know If People’s Memories Are Accurate?**

RETRIEVAL PRACTICE

RP-18 What—given the commonness of source amnesia—might life be like if we remembered all our waking experiences and all our dreams?

ANSWER: Real experiences would be confused with those we dreamed. When seeing someone we know, we might therefore be unsure whether we were reacting to something they previously did or to something we dreamed they did.

RP-19 Imagine being a jury member in a trial for a parent accused of sexual abuse based on a recovered memory. What insights from memory research should you offer the jury?

ANSWER: It will be important to remember the key points agreed upon by most researchers and professional associations: Sexual abuse, injustice, forgetting, and memory construction all

happen; recovered memories are common; memories from our first four years are unreliable; memories claimed to be recovered through hypnosis are especially unreliable; and memories, whether real or false, can be emotionally upsetting.

Improving Memory

LOQ 8-19 How can you use memory research findings to do better in this and other courses?

Biology's findings benefit medicine. Botany's findings benefit agriculture. So, too, can memory researchers' findings benefit education. Here, for easy reference, is a summary of some research-based suggestions that can help you remember information when you need it. The SQ3R—Survey, Question, Read, Retrieve, Review—study technique used in this book incorporates several of these strategies.

Rehearse repeatedly. To master material, remember the *spacing effect* and use *distributed (spaced) practice*. To learn a concept, give yourself many separate study sessions. Take advantage of life's little intervals—riding a bus, walking across campus, waiting for class to start. New memories are weak; exercise them and they will strengthen. To memorize specific facts or figures, research has shown that you should “rehearse the name or number you are trying to memorize, wait a few seconds, rehearse again, wait a little longer, rehearse again, then wait longer still and rehearse yet again. The waits should be as long as possible without losing the information” (Landauer, 2001). Reading complex material with minimal rehearsal yields little retention. Rehearsal and critical reflection help more. As the *testing effect* has shown, it pays to study actively. Taking lecture notes by hand, which requires summarizing material in your own words, leads to better retention than does verbatim laptop note taking. “The pen is mightier than the keyboard,” note researchers Pam Mueller and Daniel Oppenheimer (2014).

Make the material meaningful. You can build a network of retrieval cues by taking notes in your own words, and then increase these cues by forming as

many associations as possible. Apply the concepts to your own life. Form images. Understand and organize information. Relate the material to what you already know or have experienced. As William James (1890) suggested, “Knit each new thing on to some acquisition already there.” Mindlessly repeating someone else’s words without taking the time to really understand what they mean won’t supply many retrieval cues. On an exam, you may find yourself stuck when a question uses phrasing different from the words you memorized.

© Sigrid Olsson/PhotoAlto/Corbis

Thinking and memory Actively thinking as we read, by rehearsing and relating ideas, and by making the material personally meaningful, yields the best retention.

Activate retrieval cues. Remember the importance of *context-dependent* and *state-dependent memory*. Mentally re-create the situation and the mood in which your original learning occurred. Jog your memory by allowing one thought to cue the next.

Use mnemonic devices. Make up a story that incorporates *vivid images* of the items. *Chunk* information into acronyms. Create rhythmic rhymes (such as “i

before *e*, except after *c*”).

Minimize proactive and retroactive interference. Study before sleep. Do not schedule back-to-back study times for topics that are likely to interfere with each other, such as Spanish and French.

Sleep more. During sleep, the brain reorganizes and *consolidates* information for long-term memory. Sleep deprivation disrupts this process (Frenda et al., 2014; Lo et al., 2016). Even 10 minutes of waking rest enhances memory of what we have read (Dewar et al., 2012). So, after a period of hard study, you might just sit or lie down for a few minutes before tackling the next subject.

Test your own knowledge, both to rehearse it and to find out what you don’t yet know. The testing effect is real, and it is powerful. Don’t be lulled into overconfidence by your ability to *recognize* information. Test your *recall* using the periodic Retrieval Practice items, and the numbered Learning Objective and Master the Material questions in the Review sections. Outline sections using a blank page. Define the terms and concepts listed at each section’s end before turning back to their definitions. Take practice tests; the online resources that accompany many texts, including this text, are a good source for such tests.

RETRIEVAL PRACTICE

RP-20 Which memory strategies can help you study smarter and retain more information?

ANSWER: Spend more time rehearsing or actively thinking about the material to boost long-term recall. Schedule spaced (not crammed) study times. Make the material personally meaningful, with well-organized and vivid associations. Refresh your memory by returning to contexts and moods that activate retrieval cues. Use mnemonic devices. Minimize interference. Plan for a complete night’s sleep. Test yourself repeatedly—retrieval practice is a proven retention strategy.

Evaluate your own memory skills by engaging online with **Assess Your Strengths: How Might You Improve Your Memory?**

REVIEW Forgetting, Memory Construction, and Improving Memory

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

[source amnesia](#), p. 322

[déjà vu](#), p. 322

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

When forgetting is due to encoding failure, information has not been transferred from

- a. the environment into sensory memory.
- b. sensory memory into long-term memory.
- c. long-term memory into short-term memory.
- d. short-term memory into long-term memory.

Ebbinghaus' "forgetting curve" shows that after an initial decline, memory for novel information tends to

- a. increase slightly.
- b. decrease noticeably.
- c. decrease greatly.
- d. level out.

The hour before sleep is a good time to memorize information, because going to sleep after learning new material minimizes _____ interference.

Freud proposed that painful or unacceptable memories are blocked from consciousness through a mechanism called _____.

One reason false memories form is our tendency to fill in memory gaps with our reasonable guesses and assumptions, sometimes based on misleading information. This tendency is an example of

- a. proactive interference.
- b. the misinformation effect.
- c. retroactive interference.
- d. the forgetting curve.

Eliza's family loves to tell the story of how she "stole the show" as a 2-year-old, dancing at her aunt's wedding reception. Even though

she was so young, Eliza says she can recall the event clearly. How is this possible?

We may recognize a face at a social gathering but be unable to remember how we know that person. This is an example of _____.

When a situation triggers the feeling that “I’ve been here before,” you are experiencing _____.

Children can be accurate eyewitnesses if

- a. interviewers give the children hints about what really happened.
- b. a neutral person asks nonleading questions soon after the event.
- c. the children have a chance to talk with involved adults before the interview.
- d. interviewers use precise technical and medical terms.

Psychologists involved in the study of memories of abuse tend to *disagree* with each other about which of the following statements?

- a. Memories of events that happened before age 4 are not reliable.
- b. We tend to repress extremely upsetting memories.
- c. Memories can be emotionally upsetting.
- d. Sexual abuse happens.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

THINKING CRITICALLY ABOUT: The Fear Factor

Thinking Creatively

Do Other Species Share Our Cognitive Skills?

Language and Thought

Language Structure

Language Acquisition and Development

The Brain and Language

Do Other Species Have Language?

Thinking and Language

Throughout history, we humans have both celebrated our wisdom and bemoaned our foolishness. The poet T. S. Eliot was struck by “the hollow men . . . Headpiece filled with straw.” But Shakespeare’s Hamlet extolled the human species as “noble in reason! . . . infinite in faculties! . . . in apprehension how like a god!” Elsewhere in this text, we have likewise marveled at both our abilities and our errors.

We have studied the human brain—three pounds of wet tissue the size of a small cabbage, yet containing staggeringly complex circuitry. We have appreciated the amazing abilities of newborns. We have marveled at our visual system, which converts physical stimuli into nerve impulses, distributes them for parallel processing, and reassembles them into colorful perceptions. We have pondered our memory’s enormous capacity, and the ease with which our two-track mind processes information, with and without our awareness. Little wonder that our species has had the collective genius to invent the camera, the car, and the computer; to unlock the atom and crack the genetic code; to travel out to space and into our brain’s depths.

Yet we have also seen that in some other ways we are less than noble in reason. Our species is kin to the other animals, influenced by the same principles that produce learning in rats and pigeons. We have noted that we not-so-wise humans are easily deceived by perceptual illusions, pseudopsychic claims, and false memories.

In this chapter, we encounter further instances of these two aspects of the human condition—the rational and the irrational. We will consider thinking, and how we use—and sometimes ignore or misuse—information about the world around us. We will look at our gift for language and consider how and why it develops. And we will reflect on how deserving we are of our species name, *Homo sapiens*—wise human.

Thinking

Concepts

LOQ LEARNING OBJECTIVE QUESTION 9-1 What is *cognition*, and

what are the functions of concepts?

Psychologists who study **cognition** focus on the mental activities associated with thinking, knowing, remembering, and communicating information. One of these activities is forming **concepts**—mental groupings of similar objects, events, ideas, or people. The concept *chair* includes many items—a baby’s high chair, a reclining chair, a dentist’s chair—all for sitting. Concepts simplify our thinking. Imagine life without them. We could not ask a child to “throw the ball” because there would be no concept of *throw* or *ball*. Instead of saying, “They were angry,” we would have to describe expressions, intensities, and words. Concepts such as *ball* and *anger* give us much information with little cognitive effort.

cognition all the mental activities associated with thinking, knowing, remembering, and communicating.

concept a mental grouping of similar objects, events, ideas, or people.

We often form our concepts by developing **prototypes**—a mental image or best example of a category (Rosch, 1978). People more quickly agree that “a crow is a bird” than that “a penguin is a bird.” For most of us, the crow is the birdier bird; it more closely resembles our *bird* prototype. Similarly, for people in modern multiethnic Germany, Caucasian Germans are more prototypically German (Kessler et al., 2010). When something closely matches our prototype of a concept—such as a bird or a German—we more readily recognize it as an example of the concept.

prototype a mental image or best example of a category. Matching new items to a prototype provides a quick and easy method for sorting items into categories (as when comparing feathered creatures to a prototypical bird, such as a robin).

"Attention, everyone! I'd like to introduce the newest member of our family."

Jeff Kaufman The New Yorker Collection/
The Cartoon Bank

When we categorize people, we mentally shift them toward our category prototypes. Such was the experience of Belgian students who viewed ethnically blended faces. When viewing a blended face in which 70 percent of the features were Caucasian and 30 percent were Asian, the students categorized the face as Caucasian (**FIGURE 9.1**). Later, as their memory shifted toward the Caucasian prototype, they were more likely to remember an 80 percent Caucasian face than the 70 percent Caucasian face they had actually seen (Corneille et al., 2004). Likewise, if shown a 70 percent Asian face, they later remembered a more prototypically Asian face. So, too, with gender: People who viewed 70 percent male faces categorized them as male (no surprise there) and then later misremembered them as even more prototypically male (Huart et al., 2005).

FIGURE 9.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
FaceGen TM

FIGURE 9.1 Categorizing faces influences recollection

Shown a face that was 70 percent Caucasian, people tended to classify

the person as Caucasian and to recollect the face as more Caucasian than it was. (Recreation of experiment courtesy of Olivier Corneille.)

Move away from our prototypes, and category boundaries may blur. Is a tomato a fruit? Is a 16-year-old female a girl or a woman? Is a whale a fish or a mammal? Because a whale fails to match our *mammal* prototype, we are slower to recognize it as a mammal. Similarly, when symptoms don't fit one of our disease prototypes, we are slow to perceive an illness (Bishop, 1991). People whose heart attack symptoms (shortness of breath, exhaustion, a dull weight in the chest) don't match their *heart attack* prototype (sharp chest pain) may not seek help. And when behaviors don't fit our *discrimination* prototypes—of White against Black, male against female, young against old—we often fail to notice prejudice. People more easily detect male prejudice against females than female against males or female against females (Cunningham et al., 2009; Inman & Baron, 1996). Although concepts speed and guide our thinking, they don't always make us wise.

Problem Solving: Strategies and Obstacles

LOQ 9-2 What cognitive strategies assist our problem solving, and what obstacles hinder it?

One tribute to our rationality is our problem-solving skill. What's the best route around this traffic jam? How should we handle a friend's criticism? How can we get in the house without our keys?

Some problems we solve through *trial and error*. Thomas Edison tried thousands of light bulb filaments before stumbling upon one that worked. For other problems, we use [algorithms](#), step-by-step procedures that guarantee a solution. But step-by-step algorithms can be laborious and exasperating. To find a word using the 10 letters in *SPLOYOCHYG*, for example, you could try each letter in each of the 10 positions—907,200 permutations in all. Rather than give you a computing brain the size of a beach ball, nature resorts to [heuristics](#), simpler thinking strategies. Thus, you might reduce the number of options in the *SPLOYOCHYG* example by grouping letters that often appear together (*CH* and *GY*) and excluding rare letter combinations (such as *YY*). By using heuristics and then applying trial and error, you may hit on the answer. Have you guessed it?¹

algorithm a methodical, logical rule or procedure that guarantees solving a particular problem. Contrasts with the usually speedier—but also more error-prone—use of *heuristics*.

heuristic a simple thinking strategy that often allows us to make judgments and solve problems efficiently; usually speedier but also more error-prone than an *algorithm*.

Sometimes we puzzle over a problem and the pieces suddenly fall together in a flash of **insight**—an abrupt, true-seeming, and often satisfying solution (Topolinski & Reber, 2010). Ten-year-old Johnny Appleton had one of these Aha! moments and solved a problem that had stumped construction workers: how to rescue a young robin from a narrow 30-inch-deep hole in a cement-block wall. Johnny's solution: Slowly pour in sand, giving the bird enough time to keep its feet on top of the constantly rising pile (Ruchlis, 1990).

insight a sudden realization of a problem's solution; contrasts with strategy-based solutions.

Brain scans (EEGs or fMRIs) show bursts of activity associated with sudden flashes of insight (Kounios & Beeman, 2014). In one study, researchers asked people to think of a word that forms a compound word or phrase with each of three other words in a set (such as *pine*, *crab*, and *sauce*) and to press a button to sound a bell when they knew the answer. (Need a hint? The word is a fruit.²) A sudden Aha! insight led to about half the solutions. Before the Aha! moment, the problem solvers' frontal lobes (involved in focusing attention) were active. At the instant of discovery, there was a burst of activity in the right temporal lobe, just above the ear (**FIGURE 9.2**).

FIGURE 9.2 Myers/DeWall, *Psychology*, 12e,

From Mark Jung-Beeman, Northwestern University, and
John Kounios, Drexel University

FIGURE 9.2 The Aha! moment

A burst of right temporal lobe activity accompanied insight solutions to word problems (Jung-Beeman et al., 2004). The red dots designate EEG electrodes. The light gray lines show the distribution of high-frequency activity accompanying insight. The insight-related activity is centered in the right temporal lobe (yellow area).

Insight strikes suddenly, with no prior sense of “getting warmer” or feeling close to a solution (Knoblich & Oellinger, 2006; Metcalfe, 1986). When the answer pops into mind (*apple!*), we feel a happy sense of satisfaction. The joy of a joke may similarly lie in our sudden comprehension of an unexpected ending or a double meaning: “You don’t need a parachute to skydive. You only need a parachute to skydive twice.” Comedian Groucho Marx was a master at this: “I once shot an elephant in my pajamas. How he got in my pajamas I’ll never know.”

Insightful as we are, other cognitive tendencies may lead us astray. **Confirmation bias**, for example, leads us to seek evidence *for* our ideas more eagerly than we seek evidence *against* them (Klayman & Ha, 1987; Skov & Sherman, 1986). In a now-classic study, Peter Wason (1960) gave British university students a set of three-numbers (2-4-6) and told them the series was based on a rule. Their task was to guess the rule. (It was simple: any three ascending numbers.) Before submitting answers, students generated

their own three-number sets, and Wason told them whether their sets conformed to his rule. Once *certain* they had the rule, they could announce it. The result? Most students formed a wrong idea (“*Maybe it’s counting by twos*”) and then searched only for confirming evidence (by testing 6-8-10, 100-102-104, and so forth). Seldom right but never in doubt.

confirmation bias a tendency to search for information that supports our preconceptions and to ignore or distort contradictory evidence.

“Ordinary people,” said Wason (1981), “evade facts, become inconsistent, or systematically defend themselves against the threat of new information relevant to the issue.” Thus, having formed a belief—that vaccines cause (or do not cause) autism spectrum disorder, that people can (or cannot) change their sexual orientation, that gun control does (or does not) save lives—we prefer information that supports our belief. And once we get hung up on an incorrect view of a problem, it’s hard to approach it from a different angle. This obstacle to problem solving is called **fixation**, an inability to come to a fresh perspective. See if fixation prevents you from solving the matchstick problem in **FIGURE 9.3**. (For the solution, see **FIGURE 9.4**.)

fixation in thinking, the inability to see a problem from a new perspective; an obstacle to problem solving.

FIGURE 9.4 Solution to the matchstick problem

To solve this problem, you must view it from a new perspective, breaking the fixation of limiting solutions to two dimensions.

S.H. Chambers

“The human understanding, when any proposition has been once laid down . . . forces everything else to add fresh support and confirmation.”

Francis Bacon, *Novum Organum*, 1620

A prime example of fixation is **mental set**, our tendency to approach a problem with the mind-set of what has worked for us previously. Indeed, solutions that worked in the past often do work on new problems. Consider:

Given the sequence *O-T-T-F-?-?-?*, what are the final three letters?

Most people have difficulty recognizing that the three final letters are *F*(ive), *S*(ix), and *S*(even). But solving this problem may make the next one easier:

Given the sequence *J-F-M-A-?-?-?*, what are the final three letters? (If you

don't get this one, ask yourself what month it is.)

As a *perceptual set* predisposes what we perceive, a mental set predisposes how we think. Sometimes this can be an obstacle to problem solving, as when our mental set from our past experiences with matchsticks predisposes us to arrange them in two dimensions.

mental set a tendency to approach a problem in one particular way, often a way that has been successful in the past.

Forming Good (and Bad) Decisions and Judgments

LOQ 9-3 What is *intuition*, and how can the availability and representativeness heuristics influence our decisions and judgments?

When making each day's hundreds of judgments and decisions (*Should I take a jacket? Can I trust this person? Should I shoot the basketball or pass to the player who's hot?*), we seldom take the time and effort to reason systematically. We follow our **intuition**, our fast, automatic, unreasoned feelings and thoughts. After interviewing policy makers in government, business, and education, social psychologist Irving Janis (1986) concluded that they "often do not use a reflective problem-solving approach. How do they usually arrive at their decisions? If you ask, they are likely to tell you . . . they do it mostly by the *seat of their pants*."

intuition an effortless, immediate, automatic feeling or thought, as contrasted with explicit, conscious reasoning.

"The problem is I can't tell the difference between a deeply wise, intuitive nudge from the Universe and one of my own bone-headed ideas!"

Bradford Veley via CartoonStock -
www.cartoonstock.com/cartoonview.asp?catref=bven871

Two Quick But Risky Shortcuts

When we need to make snap judgments, heuristics enable quick thinking without conscious awareness, and they usually serve us well (Gigerenzer, 2015). But as research by cognitive psychologists Amos Tversky and Daniel Kahneman (1974) on the *representativeness* and *availability heuristics* has shown, these intuitive mental shortcuts can lead even the smartest people into dumb decisions.³

Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

“In creating these problems, we didn’t set out to fool people. All our problems fooled us, too.” Amos Tversky (1985)

Carsten Rehder/KIEL/European
Pressphoto Agency/Newscom

“Intuitive thinking [is] fine most of the time. . . . But sometimes that habit of mind gets us in trouble.” Daniel Kahneman (2005b)

THE REPRESENTATIVENESS HEURISTIC To judge the likelihood of something by intuitively comparing it to particular prototypes is to use the [representativeness heuristic](#). Imagine someone who is short, slim, and likes to read poetry. Is this person more likely to be an Ivy League university English professor or a truck driver (Nisbett & Ross, 1980)?

representativeness heuristic estimating the likelihood of events in terms of how well they seem to represent, or match, particular prototypes; may lead us to ignore other relevant information.

Many people guess English professor—because the person better fits their prototype of nerdy professor than of truck driver. In doing so, they fail to consider the *base rate* number of Ivy League English professors (fewer than 400) and truck drivers (3.5 million in the United States alone). Thus, even if the description is 50 times more typical of English professors than of truck drivers, the fact that there are about 7000 times more truck drivers means that the poetry reader is many times more likely to be a truck driver.

Some prototypes have social consequences. Consider the reaction of some non-Arab travelers soon after 9/11, when a young male of Arab descent boarded their plane. The young man fit (represented) their “terrorist” prototype, and the representativeness heuristic kicked in. His presence evoked anxiety among his fellow passengers—even though nearly 100 percent of those who fit this prototype are peace-loving citizens. One mother of two Black and three White teens asks other parents, “Do store personnel follow your children when they are picking out their Gatorade flavors? They didn’t follow my White kids. . . . When your kids trick-or-treat dressed as a ninja and a clown, do they get asked who they are with and where they live, door after door? My White kids didn’t get asked. Do your kids get pulled out of the TSA line time and again for additional screening? My White kids didn’t” (Roper, 2016). If people have a prototype—a stereotype—of delinquent Black teens, they may unconsciously use the representativeness heuristic when judging individuals. The result, even if unintended, is racism.

THE AVAILABILITY HEURISTIC The [availability heuristic](#) operates when we estimate how common an event is *based on its mental availability*. Anything that makes information pop into mind—its vividness, recency, or

distinctiveness—can make it seem commonplace. Casinos know this. They entice us to gamble by broadcasting wins with noisy bells and flashing lights. The big losses are soundlessly invisible. The availability heuristic can also distort our judgments of other people. If people from a particular ethnic or religious group commit a terrorist act, as seen in pictures of innocent people about to be beheaded, our readily available memory of the dramatic event may shape our impression of the whole group. Terrorists aim to evoke excessive terror. If terrorists were to kill 1000 people in the United States this year, Americans would be mighty afraid. Yet they would have reason to be 30 times more afraid of homicidal, suicidal, and accidental death by guns, which take more than 30,000 lives annually. In 2015 and again in 2016, feared Islamic terrorists shot and killed fewer Americans than did armed toddlers (Ingraham, 2016; LaCapria, 2015). The bottom line: *We often fear the wrong things.* (See [Thinking Critically About: The Fear Factor](#)).

1. National Safety Council, 2016. 2. Gigerenzer, 2004, 2006; Gaissmater & Gigerenzer, 2012. 3. Daley, 2011. 4. Xu et al., 2016. 5. Schneier, 2007. Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

availability heuristic estimating the likelihood of events based on their availability in memory; if instances come readily to mind (perhaps because of their vividness), we presume such events are common.

“Kahneman and his colleagues and students have changed the way we think about the way people think.”

American Psychological Association President Sharon Brehm, 2007

ALEPPO MEDIA CENTER/picture-alliance/dpa/AP Images

The power of a vivid example

The unforgettable (cognitively available) photo of 4-year-old Omran Daqneesh—dazed after being pulled from the rubble of yet another air strike in Aleppo, Syria—did more than an armload of statistics to awaken Western nations to the plight of Syrian migrants fleeing violence.

“Don’t believe everything you think.”

Bumper sticker

To offer a vivid depiction of climate change, Cal Tech scientists created an interactive map of global temperatures over the past 120 years. (See tinyurl.com/TempChange.)

Meanwhile, the lack of available images of future climate change disasters

—which some scientists regard as “Armageddon in slow motion”—has left many people unconcerned (Pew, 2014a). What’s more cognitively available than slow climate change is our recently experienced local weather, which tells us nothing about long-term planetary trends (Egan & Mullin, 2012; Kaufmann et al., 2017; Zaval et al., 2014). Unusually hot local weather increases people’s worry about global climate warming, while a recent cold day reduces their concern and overwhelms less memorable scientific data (Li et al., 2011). After Hurricane Sandy devastated New Jersey, its residents’ vivid experience of extreme weather increased their environmentalism (Rudman et al., 2013).

Over 40 nations have sought to harness the positive power of vivid, memorable images by putting eye-catching warnings and graphic photos on cigarette packages (Riordan, 2013). This campaign has worked because we reason emotionally (Huang et al., 2013). We overfeel and underthink (Slovic, 2007). In one study, Red Cross donations to Syrian refugees were 55 times greater in response to the publication of an iconic photo of a child killed compared with statistics describing the hundreds of thousands of other refugee deaths (Slovic et al., 2017). Dramatic outcomes make us gasp; probabilities we hardly grasp.

RETRIEVAL PRACTICE

RP-1 Why can news be described as “something that hardly ever happens”? How does knowing this help us assess our fears?

ANSWER: If a tragic event such as a plane crash makes the news, it is noteworthy and unusual, unlike much more common bad events, such as traffic accidents. Knowing this, we can worry less about unlikely events and think more about improving the safety of our everyday activities. (For example, we can wear a seat belt when in a vehicle and use the crosswalk when walking.)

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Availability heuristic

With scenes from the 2015 terrorist attacks in Paris, San Bernardino (California), and elsewhere flooding people's minds, 27 percent of Americans identified terrorism as their biggest worry—up from 8 percent just before the Paris attacks (Reuters, 2015). This hijacking of our rationality by fears of terrorist guns (when other risks, such as driving or influenza, kill so many more) illustrates how we often fear the wrong things.

Overconfidence

LOQ 9-5 How are our decisions and judgments affected by overconfidence, belief perseverance, and framing?

Sometimes our decisions and judgments go awry simply because we are more confident than correct. Across various tasks, people overestimate their performance (Metcalfe, 1998). If 60 percent of people correctly answer a factual question, such as “Is absinthe a liqueur or a precious stone?” they will typically average 75 percent confidence (Fischhoff et al., 1977). (It’s a licorice-flavored liqueur.) This tendency to overestimate the accuracy of our knowledge and judgments is **overconfidence**. Those who are wrong are especially vulnerable to overconfidence. One experiment gave students various physics and logic problems. Students who falsely thought a ball would continue following a curved path when rolling out of a curved tube were virtually as confident as those who correctly discerned that the ball, like

water from a curled hose, would follow a straight path (Williams et al., 2013).

overconfidence the tendency to be more confident than correct—to overestimate the accuracy of our beliefs and judgments.

Hofstadter's Law: It always takes longer than you expect, even when you take into account Hofstadter's Law.

Douglas Hofstadter, *Gödel, Escher, Bach: The Eternal Golden Braid*, 1979

It is overconfidence that drives stockbrokers and investment managers to market their ability to outperform stock market averages—which, as a group, they cannot (Malkiel, 2016). A purchase of stock *X*, recommended by a broker who judges this to be the time to buy, is usually balanced by a sale made by someone who judges this to be the time to sell. Despite their confidence, buyer and seller cannot both be right. And it is overconfidence that so often leads us to succumb to a *planning fallacy*—overestimating our future leisure time and income (Zauberman & Lynch, 2005). Students and others often expect to finish assignments ahead of schedule (Buehler et al., 1994, 2002). In fact, such projects generally take about twice the predicted time. Anticipating how much more time we will have next month, we happily accept invitations. And believing we'll surely have more money next year, we take out loans or buy on credit. Despite our past overconfident predictions, we remain overly confident of our next prediction.

“When you know a thing, to hold that you know it; and when you do not know a thing, to allow that you do not know it; this is knowledge.”

Confucius (551–479 B.C.E.), *Analects*

Overconfidence—the bias that Kahneman (2015), if given a magic wand, would most like to eliminate—can feed extreme political views. History is full of leaders who, when waging war, were more confident than correct. One research team tested 743 intelligence analysts' ability to predict future events

—predictions that typically are overconfident. Those whose predictions most often failed tended to be inflexible and closed-minded (Mellers et al., 2015). Ordinary citizens with only a shallow understanding of complex proposals, such as for cap-and-trade carbon emissions or a flat tax, may also express strong views. (Sometimes the less we know, the more definite we sound.) Asking such people to explain the details of these policies exposes them to their own ignorance, which in turn leads them to express more moderate views (Fernbach et al., 2013). To confront one's own ignorance is to become wiser.

Bianca Moscatelli/Worth Publishers

Predict your own behavior

When will you finish reading this module?

Nevertheless, overconfidence sometimes has adaptive value. Believing that their decisions are right and they have time to spare, self-confident people tend to live more happily. They make tough decisions more easily, and they seem competent (Anderson et al., 2012). Given prompt and clear feedback we can also learn to be more realistic about the accuracy of our judgments (Fischhoff, 1982). That's true of weather forecasters: Extensive feedback has enabled them to estimate their forecast accuracy ("a 60 percent

chance of rain”). The wisdom to know when we know a thing and when we do not is born of experience.

Belief Perseverance

Our overconfidence is startling. Equally so is our [belief perseverance](#)—our tendency to cling to our beliefs in the face of contrary evidence. A classic study of belief perseverance engaged people with opposing views of capital punishment (Lord et al., 1979). After studying two supposedly new research findings, one supporting and the other refuting the claim that the death penalty deters crime, each side was more impressed by the study supporting its own beliefs. And each readily disputed the other study. Thus, showing the pro- and anti-capital-punishment groups the *same* mixed evidence actually *increased* their disagreement. Rather than using evidence to draw conclusions, they used their conclusions to assess evidence—a phenomenon also known as *motivated reasoning*.

belief perseverance clinging to one’s initial conceptions after the basis on which they were formed has been discredited.

In other studies and in everyday life, people have similarly welcomed belief-supportive evidence—about climate change, same-sex marriage, or politics—while discounting challenging evidence (Friesen et al., 2015; Sunstein et al., 2016). In the late 1980s, most Democrats believed that inflation had risen under Republican President Reagan (it had dropped). In 2016, two-thirds of Republicans surveyed said that unemployment had increased and the stock market had dropped under President Obama (unemployment had plummeted and the stock market had nearly tripled). In each case, politics overrode facts (Public Policy Polling, 2016). Big time. As an old Chinese proverb says, “Two-thirds of what we see is behind our eyes.”

To rein in belief perseverance, a simple remedy exists: *Consider the opposite*. When the same researchers repeated the capital-punishment study, they asked some participants to be “as *objective* and *unbiased* as possible” (Lord et al., 1984). The plea did nothing to reduce biased evaluations of evidence. They also asked another group to consider “whether you would

have made the same high or low evaluations had exactly the same study produced results on the *other* side of the issue.” Having imagined and pondered *opposite* findings, these people became much less biased.

The more we come to appreciate why our beliefs might be true, the more tightly we cling to them. Once we have explained to ourselves why candidate X or Y will be a better commander-in-chief, we tend to ignore evidence undermining our belief. Once beliefs form and get justified, it takes more compelling evidence to change them than it did to create them. Prejudice persists. Beliefs often persevere.

"I'm sorry, Jeannie, your answer was correct, but Kevin shouted his incorrect answer over yours, so he gets the points."

Joe Dator The New Yorker Collection/The Cartoon Bank

The Effects of Framing

Framing—the way we present an issue—can be a powerful tool of persuasion. Governments know this. People are more supportive of “gun safety” than “gun control” laws, more welcoming of “undocumented workers” than of “illegal aliens,” more agreeable to a “carbon offset” fee than to a “carbon tax,” and more accepting of “enhanced interrogation” than of “torture.” And consider how the framing of options can nudge people toward beneficial decisions (Bohannon, 2016; Fox & Tannenbaum, 2015; Thaler & Sunstein, 2008):

- *Choosing to live or die.* Imagine two surgeons explaining the risk of an upcoming surgery. One explains that during this type of surgery, 10 percent of people die. The other explains that 90 percent survive. The information is the same. The effect is not. In real-life surveys, patients and

physicians overwhelmingly say the risk is greater when they hear that 10 percent *die* (Marteau, 1989; McNeil et al., 1988; Rothman & Salovey, 1997).

- *Becoming an organ donor.* In many European countries, as well as in the United States, people renewing their driver's license can decide whether to be organ donors. In some countries, the default option is *Yes*, but people can opt out. Nearly 100 percent of the people in opt-out countries have agreed to be donors. In countries where the default option is *No*, most do *not* agree to be donors (Hajhosseini et al., 2013; Johnson & Goldstein, 2003).
- *Opting to save for retirement.* U.S. companies once required employees who wanted to contribute to a retirement plan to choose a lower take-home pay, which few people did. Thanks to a new law, they can now automatically enroll their employees in the plan but allow them to opt out. Either way, the decision to contribute is the employee's. But under the new "opt-out" arrangement, enrollments in one analysis of 3.4 million workers soared from 59 to 86 percent (Rosenberg, 2010). Britain's 2012 change to an opt-out framing similarly led to 5 million more retirement savers (Halpern, 2015).

framing the way an issue is posed; how an issue is framed can significantly affect decisions and judgments.

The point to remember: Framing can nudge our attitudes and decisions.

The Perils and Powers of Intuition

LOQ 9-6 How do smart thinkers use intuition?

We have seen how our unreasoned intuition can plague our efforts to solve problems, assess risks, and make wise decisions. The perils of intuition can persist even when people are offered extra pay for thinking smart, even when they are asked to justify their answers, and even among expert physicians, clinicians, and U.S. federal intelligence agents (Reyna et al., 2014; Shafir & LeBoeuf, 2002; Stanovich et al., 2013). Very smart people can make not-so-

smart judgments.

So, are our heads indeed filled with straw? Good news: Cognitive scientists are also revealing intuition's powers:

- *Intuition is analysis “frozen into habit”* (Simon, 2001). It is implicit (unconscious) knowledge—what we’ve recorded in our brains but can’t fully explain (Chassy & Gobet, 2011; Gore & Sadler-Smith, 2011). We see this ability to size up a situation and react in an eyeblink in chess masters playing speed chess, as they intuitively know the right move (Burns, 2004). We see it in the smart and quick judgments of experienced nurses, firefighters, art critics, and car mechanics. We see it in skilled athletes who react *without thinking*. Indeed, conscious thinking may disrupt well-practiced movements, leading skilled athletes to choke under pressure, as when shooting free throws (Beilock, 2010). And we would see this instant intuition in you, too, for anything in which you have developed knowledge based on experience.
- *Intuition is usually adaptive, enabling quick reactions*. Our fast and frugal heuristics let us intuitively assume that fuzzy-looking objects are far away—which they usually are, except on foggy mornings. Our learned associations surface as gut feelings, right or wrong: Seeing a stranger who looks like someone who has harmed or threatened us in the past, we may automatically react with distrust. Newlyweds’ implicit attitudes toward their new spouses likewise predict their future marital happiness (McNulty et al., 2013).
- *Intuition is huge*. Unconscious, automatic influences are constantly affecting our judgments (Custers & Aarts, 2010). Consider: Most people guess that the more complex the choice, the smarter it is to make decisions rationally rather than intuitively (Inbar et al., 2010). Actually, in making complex decisions, we sometimes benefit by letting our brain work on a problem without consciously thinking about it (Strick et al., 2010, 2011). In one series of experiments, three groups of people read complex information (for example, about apartments or European football matches). Those in the first group stated their preference immediately after reading information about four possible options. The second group, given several minutes to analyze the information, made slightly smarter decisions. But wisest of all, in several studies, were those in the third group, whose attention was distracted for a time, enabling their minds to engage in

automatic, unconscious processing of the complex information. The practical lesson: Letting a problem incubate while we attend to other things can pay dividends (Dijksterhuis & Strick, 2016). Facing a difficult decision involving a lot of facts, we're wise to gather all the information we can, and then say, "Give me some time *not* to think about this, even to sleep on it." Thanks to our ever-active brain, nonconscious thinking (reasoning, problem solving, decision making, planning) can be surprisingly astute (Creswell et al., 2013; Hassin, 2013; Lin & Murray, 2015). Critics note that some studies have not found the supposed power of unconscious thought, and they remind us that deliberate, conscious thought also furthers smart thinking (Newell, 2015; Nieuwenstein et al., 2015; Phillips et al., 2016). In challenging situations, superior decision makers, including chess players, take time to think (Moxley et al., 2012). And with many sorts of problems, deliberative thinkers are aware of the intuitive option, but know when to override it (Mata et al., 2013). Consider two problems:

"The heart has its reasons which reason does not know."

Blaise Pascal, *Pensees*, 1670

1. A bat and a ball together cost 110 cents. The bat costs 100 cents more than the ball. How much does the ball cost?
2. If it takes 5 machines 5 minutes to make 5 widgets, how long would it take 100 machines to make 100 widgets?

Most people's intuitive responses—10 cents and 100 minutes—are wrong, and a few moments of deliberate thinking reveals why.⁴

The bottom line: Our two-track mind makes sweet harmony as smart, critical thinking listens to the creative whispers of our vast unseen mind and then evaluates evidence, tests conclusions, and plans for the future.

Thinking Creatively

LOQ 9-7 What is *creativity*, and what fosters it?

Creativity is the ability to produce ideas that are both novel and valuable

(Hennessey & Amabile, 2010). Consider Princeton mathematician Andrew Wiles' incredible, creative moment. Pierre de Fermat, a seventeenth-century mischievous genius, had challenged mathematicians of his day to match his solutions to various number theory problems. His most famous challenge—*Fermat's last theorem*—baffled the greatest mathematical minds, even after a \$2 million prize (in today's dollars) was offered in 1908 to whoever first created a proof.

creativity the ability to produce new and valuable ideas.

Wiles had pondered Fermat's theorem for more than 30 years and had come to the brink of a solution. One morning in 1994, out of the blue, the final "incredible revelation" struck him. "It was so indescribably beautiful; it was so simple and so elegant. I couldn't understand how I'd missed it. . . . It was the most important moment of my working life" (Singh, 1997, [p. 25](#)).

Creativity like Wiles' is supported by a certain level of *aptitude* (ability to learn). Those who score exceptionally high in quantitative aptitude as 13-year-olds, for example, are later more likely to create published or patented work (Park et al., 2008; Robertson et al., 2010). Yet there is more to creativity than aptitude, or what intelligence tests reveal. Indeed, brain activity associated with intelligence differs from that associated with creativity (Jung & Haier, 2013). Aptitude tests (such as the SAT) typically require [convergent thinking](#)—an ability to provide a single correct answer.

convergent thinking narrowing the available problem solutions to determine the single best solution.

Creativity tests (*How many uses can you think of for a brick?*) require [divergent thinking](#)—the ability to consider many different options and to think in novel ways. Injury to certain areas of the frontal lobes can leave reading, writing, and arithmetic skills intact but destroy imagination (Kolb & Whishaw, 2006).

divergent thinking expanding the number of possible problem solutions; creative thinking that diverges in different directions.

PETER MUHLY/Getty Images

Industrious creativity

Researcher Sally Reis (2001) found that notably creative women were typically “intelligent, hard working, imaginative, and strong willed” as girls, noting examples such as Nobel Prize-winning geneticist Barbara McClintock. In her acceptance speech for the 2013 Nobel Prize for Literature, author Alice Munro, shown here, also spoke about creativity as hard work. “Stories are so important in the world. . . . [The part that’s hardest is] when you go over the story and realize how bad it is. You know, the first part, excitement, the second, pretty good, but then you pick it up one morning and you think, ‘what nonsense,’ and that is when you really have to get to work on it. And for me, it always seemed the right thing to do.”

Robert Sternberg and his colleagues believe creativity has five components (Sternberg, 1988, 2003; Sternberg & Lubart, 1991, 1992):

1. **Expertise**—well-developed knowledge—furnishes the ideas, images, and phrases we use as mental building blocks. “Chance favors only the prepared mind,” observed Louis Pasteur. The more blocks we have, the more chances we have to combine them in novel ways. Wiles’ well-developed knowledge put the needed theorems and methods at his disposal.
2. **Imaginative thinking skills** provide the ability to see things in novel ways, to recognize patterns, and to make connections. Having mastered a problem’s basic elements, we can redefine or explore it in a new way. Copernicus first developed expertise regarding the solar system and its planets, and then creatively defined the system as revolving around the Sun, not the Earth. Wiles’ imaginative solution combined two partial solutions.
3. **A venturesome personality** seeks new experiences, tolerates ambiguity and risk, and perseveres in overcoming obstacles. Wiles said he labored in near-isolation from the mathematics community partly to stay focused and avoid distraction. Such determination is an enduring trait.
4. **Intrinsic motivation** is the quality of being driven more by interest, satisfaction, and challenge than by external pressures (Amabile & Hennessey, 1992). Creative people focus less on extrinsic motivators—meeting deadlines, impressing people, or making money—than on the pleasure and stimulation of the work itself. Asked how he solved such difficult scientific problems, Isaac Newton reportedly answered, “By thinking about them all the time.” Wiles concurred: “I was so obsessed by this problem that . . . I was thinking about it all the time—[from] when I woke up in the morning to when I went to sleep at night” (Singh & Riber, 1997).
5. **A creative environment** sparks, supports, and refines creative ideas. Wiles stood on the shoulders of others and collaborated with a former student. A study of the careers of 2026 prominent scientists and inventors revealed that the most eminent were mentored, challenged, and supported by their colleagues (Simonton, 1992). Creativity-fostering environments support innovation, team building, and communication (Hülshager et al., 2009). They also minimize anxiety and foster contemplation (Byron & Khazanchi, 2011). While on a retreat in a monastery, Jonas Salk solved a problem that led to the polio vaccine. Later, when he designed the Salk Institute, he provided contemplative

spaces where scientists could work without interruption (Sternberg, 2006).

The Cartoon Bank

A creative environment

For those seeking to boost the creative process, research offers some ideas:

- *Develop your expertise.* Ask yourself what you care about and most enjoy. Follow your passion by broadening your knowledge base and becoming an expert at something.
- *Allow time for incubation.* Think hard on a problem, but then set it aside and come back to it later. For those with enough knowledge—the needed mental building blocks—a period of inattention to a problem (“sleeping on it”) allows for automatic processing to form associations (Zhong et al., 2008).
- *Set aside time for the mind to roam freely.* Creativity springs from “defocused attention” (Simonton, 2012a,b). So detach from attention-grabbing television, social networking, and video gaming. Jog, go for a long walk, or meditate. Serenity seeds spontaneity.
- *Experience other cultures and ways of thinking.* Living abroad sets the creative juices flowing. Controlled studies show that students who have spent time abroad and embraced their host culture are more adept at working out creative solutions to problems (Lee et al., 2012; Tadmor et al., 2012). Even getting out of your neighborhood and exposing yourself to multicultural experiences fosters flexible thinking (Kim et al., 2013; Ritter

et al., 2012).

Dave Coverly/Speed Bump

Imaginative thinking

Cartoonists often display creativity as they see things in new ways or make unusual connections.

"For the love of God, is there a doctor in the house?"

RETRIEVAL PRACTICE

RP-2 Match the process or strategy listed below (1–10) with its description (a–j).

1. Algorithm
 2. Intuition
 3. Insight
 4. Heuristic
 5. Fixation
 6. Confirmation bias
 7. Overconfidence
 8. Creativity
 9. Framing
 10. Belief perseverance
- a. Inability to view problems from a new angle; focuses thinking but hinders creative problem solving.
 - b. Methodological rule or procedure that guarantees a solution but requires time and effort.
 - c. Your fast, automatic, effortless feelings and thoughts based on your experience; huge and adaptive but can lead you to overfeel and underthink.
 - d. Simple thinking shortcut that enables quick and efficient decisions but puts us at risk for errors.
 - e. Sudden Aha! reaction that instantly reveals the solution.
 - f. Tendency to search for support for your own views and to ignore contradictory evidence.
 - g. Holding on to your beliefs even after they are proven wrong; closing your mind to new ideas.
 - h. Overestimating the accuracy of your beliefs and judgments; allows you to be happier and to make decisions more easily, but puts you at risk for errors.
 - i. Wording a question or statement so that it evokes a desired response; can mislead people and influence their decisions.
 - j. The ability to produce novel and valuable ideas.

ANSWER: 1. b, 2. c, 3. e, 4. d, 5. a, 6. f, 7. h, 8. j, 9. i, 10. g

For a summary of some key ideas from this section, see [TABLE 9.1](#).

TABLE 9.1

Comparing Cognitive Processes and Strategies

Process or Strategy	Description	Powers	Perils
<i>Algorithm</i>	Methodical rule or procedure	Guarantees solution	Requires time and effort
<i>Heuristic</i>	Simple thinking shortcut, such as the availability heuristic (which estimates likelihood based on how easily events come to mind)	Lets us act quickly and efficiently	Puts us at risk for errors
<i>Insight</i>	Sudden Aha! reaction	Provides instant realization of solution	May not happen
<i>Confirmation bias</i>	Tendency to search for support for our own views and ignore contradictory evidence	Lets us quickly recognize supporting evidence	Hinders recognition of contradictory evidence
<i>Fixation</i>	Inability to view problems from a new angle	Focuses thinking	Hinders creative problem solving
<i>Intuition</i>	Fast, automatic feelings	Is based on	Can lead us

	and thoughts	our experience; huge and adaptive	to overfeel and underthink
<i>Overconfidence</i>	Overestimating the accuracy of our beliefs and judgments	Allows us to be happy and to make decisions easily	Puts us at risk for errors
<i>Belief perseverance</i>	Ignoring evidence that proves our beliefs are wrong	Supports our enduring beliefs	Closes our mind to new ideas
<i>Framing</i>	Wording a question or statement so that it evokes a desired response	Can influence others' decisions	Can produce a misleading result
<i>Creativity</i>	Ability to innovate valuable ideas	Produces new insights and products	May distract from structured, routine work

Do Other Species Share Our Cognitive Skills?

LOQ 9-8 What do we know about thinking in other species?

Other animals are surprisingly smart (de Waal, 2016). In her 1908 book, *The Animal Mind*, pioneering psychologist Margaret Floy Washburn argued that animal consciousness and intelligence can be inferred from their behavior. In 2012, neuroscientists convening at the University of Cambridge added that animal consciousness can also be inferred from their brains: “Nonhuman

animals, including all mammals and birds,” possess the neural networks “that generate consciousness” (Low, 2012). Consider, then, what animal brains can do.

Mike Lovett

Animal cognition in action

Until his death in 2007, Alex, an African Grey parrot, categorized and named objects (Pepperberg, 2009, 2012, 2013). Among his jaw-dropping numerical skills was the ability to comprehend numbers up to 8. He could speak the number of objects. He could add two small clusters of objects and announce the sum. He could indicate which of two numbers was greater. And he gave correct answers when shown various groups of objects. Asked, for example, “What color four?” (meaning “What’s the color of the objects of which there are four?”), he could speak the answer.

USING CONCEPTS AND NUMBERS By touching screens in quest of a food reward, black bears have learned to sort pictures into animal and nonanimal categories, or concepts (Vonk et al., 2012). The great apes—a group that includes chimpanzees and gorillas—also form concepts, such as *cat* and *dog*. After monkeys have learned these concepts, certain frontal lobe neurons in their brain fire in response to new “cat-like” images, others to new “dog-like” images (Freedman et al., 2001). Even pigeons—mere birdbrains—can sort objects (pictures of cars, cats, chairs, flowers) into categories. Shown a picture of a never-before-seen chair, pigeons will reliably peck a key that represents *chairs* (Wasserman, 1995).

DISPLAYING INSIGHT Psychologist Wolfgang Köhler (1925) showed that humans are not the only creatures to display insight. He placed a piece of fruit and a long stick outside the cage of a chimpanzee named Sultan, beyond his reach. Inside the cage, Köhler placed a short stick, which Sultan grabbed,

using it to try to reach the fruit. After several failed attempts, the chimpanzee dropped the stick and seemed to survey the situation. Then suddenly (as if thinking “Aha!”), Sultan jumped up and seized the short stick again. This time, he used it to pull in the longer stick—which he then used to reach the fruit. Apes have even exhibited foresight by storing a tool they could use to retrieve food the next day (Mulcahy & Call, 2006). (For one example of a chimpanzee’s use of foresight, see [FIGURE 9.5a](#).) And apes have displayed an ability to read others’ minds—by anticipating where a human will look for an object, even if it’s no longer there (Krupenye et al., 2016).

FIGURE 9.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Neurology/PA/AP Photo; Chris Bird & Nathan Emery; Chris Bird & Nathan Emery

FIGURE 9.5 Animal talents

(a) One male chimpanzee in Sweden’s Furuviik Zoo was observed every morning collecting stones into a neat little pile, which later in the day he used as ammunition to pelt visitors (Osvath & Karvonen, 2012). (b) Crows studied by Christopher Bird and Nathan Emery (2009) quickly learned to raise the water level in a tube and nab a floating worm by dropping in stones. Other crows have used twigs to probe for insects, and bent strips of metal to reach food.

Birds, too, have displayed insight. One experiment, by (yes) Christopher Bird and Nathan Emery (2009), brought to life an Aesop fable in which a thirsty crow is unable to reach the water in a partly filled pitcher. See the crow’s solution (exactly as in the fable) in [Figure 9.5b](#). Other crows have fashioned wire or sticks for extracting food, such as insects in rotting logs (Rutz et al., 2016).

TRANSMITTING CULTURE Like humans, other species invent behaviors and transmit cultural patterns to their observing peers and offspring (Boesch-Achermann & Boesch, 1993). Forest-dwelling chimpanzees select different tools for different purposes—a heavy stick for making holes, a light, flexible

stick for fishing for termites, a pointed stick for roasting marshmallows. (Just kidding: They don't roast marshmallows, but they have surprised us with their sophisticated tool use [Sanz et al., 2004]). Researchers have found at least 39 local customs related to chimpanzee tool use, grooming, and courtship (Claidière & Whiten, 2012; Whiten & Boesch, 2001). One group may slurp termites directly from a stick, another group may pluck them off individually. One group may break nuts with a stone hammer, while their neighbors use a wooden hammer. One chimpanzee discovered that tree moss could absorb water for drinking from a waterhole, and within six days seven other observant chimpanzees began doing the same (Hobaiter et al., 2014). These transmitted behaviors, along with differing communication and hunting styles, are the chimpanzee version of cultural diversity.

Several experiments have brought chimpanzee and baboon cultural transmission into the laboratory (Claidière et al., 2014; Horner et al., 2006). If Chimpanzee A obtains food either by sliding or by lifting a door, Chimpanzee B will then typically do the same to get food. And so will Chimpanzee C after observing Chimpanzee B. Across a chain of six animals, chimpanzees see, and chimpanzees do.

OTHER COGNITIVE SKILLS A baboon in an 80-member troop can distinguish every other member's voice (Jolly, 2007). Great apes, dolphins, and elephants recognize themselves in a mirror, demonstrating self-awareness. Dolphins form coalitions, cooperatively hunt, and learn tool use from one another (Bearzi & Stanford, 2010). In Shark Bay, Western Australia, a small group of dolphins learned to use marine sponges as protective nose guards when probing the sea floor for fish (Krützen et al., 2005). Elephants also display their abilities to learn, remember, discriminate smells, empathize, cooperate, teach, and spontaneously use tools (Byrne et al., 2009). Chimpanzees show altruism, cooperation, and group aggression. Like humans, they will purposefully kill their neighbor to gain land, and they grieve over dead relatives (Anderson et al., 2010; Biro et al., 2010; Mitani et al., 2010).

* * *

Thinking about other species' abilities brings us back to our initial question: How deserving are we humans of the label *Homo sapiens*—wise human? Let's pause to give our species some midterm grades. On decision making

and risk assessment, our smart but error-prone species might rate a B–. On problem solving, where humans are inventive yet vulnerable to confirmation bias and fixation, we would probably receive a better mark, perhaps a B+. And on cognitive efficiency and creativity, our quick (though sometimes faulty) heuristics and divergent thinking would surely earn us an A.

REVIEW Thinking

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

A mental grouping of similar things is called a _____.

The most systematic procedure for solving a problem is a(n) _____.

Oscar describes his political beliefs as “strongly liberal,” and he is not interested in exploring opposing viewpoints. How might he be affected by confirmation bias and belief perseverance?

A major obstacle to problem solving is fixation, which is a(n)

- a. tendency to base our judgments on vivid memories.

- o. tendency to wait for insight to occur.
- o. inability to view a problem from a new perspective.
- l. rule of thumb for judging the likelihood of an event in terms of our mental image of it.

Terrorist attacks in Paris and San Bernardino made Americans, in the words of one senator, “really scared and worried”—and more fearful of being victimized by terrorism than of other greater threats. Such exaggerated fears after dramatic events illustrates the _____ heuristic.

When consumers respond more positively to ground beef described as “75 percent lean” than to the same product labeled “25 percent fat,” they have been influenced by _____.

Which of the following is NOT a characteristic of a creative person?

- a. Expertise
- o. Extrinsic motivation
- o. A venturesome personality
- l. Imaginative thinking skills

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Language and Thought

Imagine an alien species that could pass thoughts from one head to another merely by pulsating air molecules in the space between them. Perhaps these weird creatures could inhabit a future science fiction movie? Actually, we are those creatures! When we speak, our brain and voice apparatus transmit air pressure waves that we send banging against another's eardrum—enabling us to transfer thoughts from our brain into theirs. As cognitive scientist Steven Pinker (1998) noted, we sometimes sit for hours “listening to other people make noise as they exhale, because those hisses and squeaks contain *information*.” And thanks to all those funny sounds created in our heads from the air pressure waves we send out, we get people's attention. We get them to do things. And we maintain relationships (Guerin, 2003). Depending on how you vibrate the air, you may get a scowl or a kiss.

M. Spencer Green/AP Photo

Language transmits knowledge

Whether spoken, written, or signed, language—the original wireless communication—enables mind-to-mind information transfer, and with it the transmission of civilization's accumulated knowledge across generations.

Language is more than vibrating air—it is our spoken, written, or signed words, and the ways we combine them to communicate meaning. When I [DM] created this paragraph, my fingers on a keyboard generated electronic binary numbers that were translated into the squiggles in front of you. When transmitted by reflected light rays into your retina, these squiggles trigger

formless nerve impulses that travel to several areas of your brain, which integrate the information, compare it to stored information, and decode meaning. Thanks to language, information is moving from my mind to yours. Many animals know little more than what they sense. Thanks to language, we comprehend much that we've never seen and that our distant ancestors never knew. Today, notes Daniel Gilbert (2006), the average taxi driver in Pittsburgh “knows more about the universe than did Galileo, Aristotle, Leonardo, or any of those other guys who were so smart they only needed one name.”

language our spoken, written, or signed words and the ways we combine them to communicate meaning.

“The secret to our ancestors’ survival was probably our use of language to develop new modes of cooperation.”

David Grinspoon, “Can Humans Outsmart Extinction?” (2016)

Let’s begin our study of language by examining some of its components.

Language Structure

LOQ 9-9 What are the structural components of a language?

Consider how we might go about inventing a language. For a spoken language, we would need three building blocks:

- **Phonemes** are the smallest distinctive sound units in a language. To say *bat*, English speakers utter the phonemes *b*, *a*, and *t*. (Phonemes aren’t the same as letters. *That* also has three phonemes—*th*, *a*, and *t*.) Linguists surveying nearly 500 languages have identified 869 different phonemes in human speech, but no language uses all of them (Holt, 2002; Maddieson, 1984). Those 800+ sounds “can form all the words in every language of the world,” notes child language researcher Patricia Kuhl (2015). English uses about 40; other languages use anywhere from half to more than twice

that many. As a general rule, consonant phonemes carry more information than do vowel phonemes. *The treth ef thes stetement shed be evedent from thes bref demenstretien.*

- **Morphemes** are the smallest language units that carry meaning. In English, a few morphemes are also phonemes—the article *a*, for instance. But most morphemes combine two or more phonemes. Some morphemes, like *bat* or *gentle*, are words. Others—like the prefix *pre-* in *preview* or the suffix *-ed* in *adapted*—are parts of words.
- **Grammar** is a language’s set of rules that enable people to communicate. Grammatical rules guide us in deriving meaning from sounds (*semantics*) and in ordering words into sentences (*syntax*).

phoneme in a language, the smallest distinctive sound unit.

morpheme in a language, the smallest unit that carries meaning; may be a word or a part of a word (such as a prefix).

grammar in a language, a system of rules that enables us to communicate with and understand others. *Semantics* is the language’s set of rules for deriving meaning from sounds, and *syntax* is its set of rules for combining words into grammatically sensible sentences.

Like life constructed from the genetic code’s simple alphabet, language is complexity built of simplicity. In English, for example, 40 or so phonemes can be combined to form more than 100,000 morphemes, which alone or in combination produce the 600,000 variations of past and present words in the *Oxford English Dictionary*. Using those words, we can then create an infinite number of sentences, most of which (like this one) are original. I know that you can know why I worry that you think this sentence is starting to get too complex; but that complexity—and our capacity to communicate and comprehend it—is what distinguishes our human language capacity (Hauser et al., 2002; Premack, 2007).

RETRIEVAL PRACTICE

RP-3 How many morphemes are in the word *cats*? How many phonemes?

ANSWER: Two morphemes—*cat* and *s*, and four phonemes—*c*, *a*, *t*, and *s*

We humans have an astonishing knack for language. With remarkable efficiency, we sample tens of thousands of words in our memory, effortlessly assemble them with near-perfect syntax, and spew them out, three words a second (Vigliocco & Hartsuiker, 2002). Seldom do we form sentences in our minds before speaking them. Rather we organize them on the fly as we speak. And while doing all this, we also adapt our utterances to our social and cultural context. One analysis of 350 billion American English words between the years 1800 and 2000—a period of tremendous immigration—showed that language use changed to promote understanding between people from different linguistic backgrounds (Hills & Adelman, 2015). We also follow norms for speaking (*How far apart should we stand?*) and listening (*Is it OK to interrupt?*). Given how many ways there are to mess up, it's amazing that we master this social dance. How and when does it happen?

Language Acquisition and Development

To Steven Pinker (1990), language is “the jewel in the crown of cognition.” Without sight or hearing, you could still have friends and a job. But without language, could you have these things? If you were able to retain only one cognitive ability, make it language, suggested researcher Lera Boroditsky (2009): “Language is so fundamental to our experience, so deeply a part of being human, that it’s hard to imagine life without it.”

"Got idea. Talk better. Combine words. Make sentences."

Sidney Harris

Language Acquisition: How Do We Learn Language?

LOQ 9-10 How do we acquire language, and what is *universal grammar*?

Linguist Noam Chomsky has argued that language is an unlearned human trait, separate from other parts of human cognition. He theorized that a built-in predisposition to learn grammar rules, which he called *universal grammar*, helps explain why preschoolers pick up language so readily and use grammar so well. It happens so naturally—as naturally as birds learn to fly—that training hardly helps.

Other researchers note that children actually learn grammar as they discern patterns in the language they hear (Ibbotson & Tomasello, 2016). And even

Chomsky agrees that we are not born with a built-in *specific* language or *specific* set of grammatical rules. The world's languages are structurally very diverse—more so than the universal grammar idea implies (Bergen, 2014). But all human languages—and there are more than 6000 of them—have nouns, verbs, and adjectives as grammatical building blocks, and order and utter words in some common ways (Blasi et al., 2016; Futrell et al., 2015). Whatever language we experience as children, whether spoken or signed, we will readily learn its specific grammar and vocabulary (Bavelier et al., 2003). And no matter what language we learn, we start speaking it mostly in nouns (*kitty, da-da*) rather than in verbs and adjectives (Bornstein et al., 2004). Biology and experience work together.

RETRIEVAL PRACTICE

RP-4 What was the premise of researcher Noam Chomsky's work in language development?

ANSWER: Chomsky maintained that all languages share a universal grammar, and humans are biologically predisposed to learn the grammar rules of language.

© Susan Meiselas/Magnum Photos

Creating a language

Brought together as if on a desert island (actually a school), Nicaragua's young deaf children over time drew upon sign gestures from home to create their own Nicaraguan Sign Language, complete with words and

intricate grammar. Our biological predisposition for language does not create language in a vacuum. But activated by a social context, nature and nurture work creatively together (Osborne, 1999; Sandler et al., 2005; Senghas & Coppola, 2001).

Language Development: When Do We Learn Language?

LOQ 9-11 What are the milestones in language development, and when is the critical period for acquiring language?

Make a quick guess: How many words of your native language did you learn between your first birthday and your high school graduation? Although you use only 150 words for about half of what you say, you probably learned about 60,000 words (Bloom, 2000; McMurray, 2007). That averages (after age 2) nearly 3500 words each year, or nearly 10 each day! How you did it—how those 3500 words could so far outnumber the roughly 200 words your schoolteachers consciously taught you each year—is one of the great human wonders.

Could you even now state the rules of syntax (the correct way to string words together to form sentences) for the language(s) you speak fluently? Most of us cannot. Yet before you were able to add $2 + 2$, you were creating your own original sentences and applying these rules. As a preschooler, you comprehended and spoke with a facility that would put to shame college students struggling to learn a new language.

RECEPTIVE LANGUAGE Children's language development moves from simplicity to complexity. Infants start without language (*in fantis* means “not speaking”). Yet by 4 months of age, babies can recognize differences in speech sounds (Stager & Werker, 1997). They can also read lips. We know this because in experiments, babies have preferred looking at a face that matches a sound—an *ah* coming from wide open lips and an *ee* from a mouth with corners pulled back (Kuhl & Meltzoff, 1982). Recognizing such differences marks the beginning of the development of babies' *receptive language*, their ability to understand what is said to and about them.

Infants' language comprehension greatly outpaces their language production. Even at 6 months, long before speaking, many infants recognize

object names (Bergelson & Swingley, 2012, 2013). At 7 months and beyond, they grow in their power to segment spoken sounds into individual words. When adults listen to an unfamiliar language, the syllables all run together. A young Sudanese couple new to North America and unfamiliar with English might, for example, hear *United Nations* as “Uneye Tednay Shuns.” Their 7-month-old daughter would not have this problem. Human infants display a remarkable ability to learn statistical aspects of human speech (Erickson & Thiessen, 2015; Werker et al., 2012). Their brains not only discern word breaks, they statistically analyze which syllables—as in *hap-py-ba-by*—most often go together. After just two minutes of exposure to a computer voice speaking an unbroken, monotone string of nonsense syllables (*bidakupadotigolabubidaku . . .*), 8-month-olds were able to recognize (as indicated by their attention) three-syllable sequences that appeared repeatedly (Saffran, 2009; Saffran et al., 1996).

PRODUCTIVE LANGUAGE Long after the beginnings of receptive language, babies’ *productive language*—their ability to produce words—matures. Before nurture molds babies’ speech, nature enables a wide range of possible sounds in the **babbling stage**, beginning around 4 months. Many of these spontaneously uttered sounds are consonant-vowel pairs formed by simply bunching the tongue in the front of the mouth (*da-da*, *na-na*, *ta-ta*) or by opening and closing the lips (*ma-ma*), both of which babies do naturally for feeding (MacNeilage & Davis, 2000). Babbling does not imitate the adult speech babies hear—it includes sounds from various languages. From this early babbling, a listener could not identify an infant as being, say, French, Korean, or Ethiopian.

babbling stage beginning around 4 months, the stage of speech development in which an infant spontaneously utters various sounds at first unrelated to the household language.

By about 10 months old, infants’ babbling has changed so that a trained ear can identify the household language (de Boysson-Bardies et al., 1989). Deaf infants who observe their deaf parents signing begin to babble more with their hands (Petitto & Marentette, 1991). Without exposure to other languages, babies lose their ability to do what we (believe it or not) cannot—

to discriminate and produce sounds and tones found outside our native language (Kuhl et al., 2014; Meltzoff et al., 2009). Thus, by adulthood, those who speak only English cannot discriminate certain sounds in Japanese speech. Nor can Japanese adults with no training in English hear the difference between the English *r* and *l*. For a Japanese-speaking adult, *la-la-ra-ra* may sound like the same syllable repeated.

Around their first birthday, most children enter the **one-word stage**. They have already learned that sounds carry meanings, and if repeatedly trained to associate, say, *fish* with a picture of a fish, 1-year-olds will look at a fish when a researcher says, “Fish, fish! Look at the fish!” (Schafer, 2005). They now begin to use sounds—usually only one barely recognizable syllable, such as *ma* or *da*—to communicate meaning. But family members learn to understand, and gradually the infant’s language conforms more to the family’s language. Across the world, baby’s first words are often nouns that label objects or people (Tardif et al., 2008). At this one-word stage, a single inflected word (“*Doggy!*”) may equal a sentence (“*Look at the dog out there!*”).

one-word stage the stage in speech development, from about age 1 to 2, during which a child speaks mostly in single words.

At about 18 months, children’s word learning explodes from about a word per week to a word per day. By their second birthday, most have entered the **two-word stage** (TABLE 9.2). They start uttering two-word sentences in **telegraphic speech**. Like yesterday’s telegrams that charged by the word (TERMS ACCEPTED. SEND MONEY), a 2-year-old’s speech contains mostly nouns and verbs (“*Want juice*”). Also like telegrams, their speech follows rules of syntax, arranging words in a sensible order. English-speaking children typically place adjectives before nouns—*white house* rather than *house white*. Spanish reverses this order, as in *casa blanca*.

two-word stage beginning about age 2, the stage in speech development during which a child speaks mostly in two-word statements.

telegraphic speech early speech stage in which a child speaks like a telegram—"go car"—using mostly nouns and verbs.

TABLE 9.2
Summary of Language Development

Month (approximate)	Stage
4	Babbles many speech sounds ("ah-goo")
10	Babbling resembles household language ("ma-ma")
12	One-word speech ("Kitty!")
24	Two-word speech ("Get ball.")
24+	Rapid development into complete sentences

Moving out of the two-word stage, children quickly begin uttering longer phrases (Fromkin & Rodman, 1983). By early elementary school, they understand complex sentences and begin to enjoy the humor conveyed by double meanings: "You never starve in the desert because of all the sand-which-is there."

RETRIEVAL PRACTICE

RP-5 What is the difference between *receptive* and *productive* language, and when do children normally hit these milestones in language development?

ANSWER: Infants normally start developing *receptive language* skills (ability to understand what is said to and about them) around 4 months of age. Then, starting with babbling at 4 months and beyond, infants normally start building *productive language* skills (ability to produce sounds and

eventually words).

Purestock/AGE Fotostock

A natural talent

Human infants come with a remarkable capacity to soak up language. But the particular language they learn will reflect their unique interactions with others.

CRITICAL PERIODS Some children—such as those who receive a cochlear implant to enable hearing, or those who are adopted by a family in another country—get a late start on learning a particular language. For these late bloomers, language development follows the same sequence, although usually at a faster pace (Ertmer et al., 2007; Snedeker et al., 2007). But there is a limit on how long language learning can be delayed. Childhood seems to represent a *critical* (or “sensitive”) *period* for mastering certain aspects of language before the language-learning window gradually closes (Hernandez & Li, 2007; Lenneberg, 1967). Later-than-usual exposure—at age 2 or 3—unleashes the idle language capacity of a child’s brain, producing a rush of language. But by about age 7, those who have not been exposed to either a

spoken or a signed language lose their ability to master *any* language. And children exposed to low-quality language—such as 4-year-olds in classrooms with 3-year-olds, or some children from impoverished homes—often display less language skill (Ansari et al., 2015; Hirsh-Pasek et al., 2015).

Thanks to the shared human ability to learn language, Europeans and Native Australia–New Zealand populations—groups who have been geographically separated for 50,000 years—can readily learn each other’s languages (Chater et al., 2009). But if they learn that new language as adults, they will usually speak it with the accent of their native language, and they will also have difficulty mastering the new grammar. In one experiment, Korean and Chinese immigrants considered 276 English sentences (“*Yesterday the hunter shoots a deer*”) and decided whether they were grammatically correct or incorrect (Johnson & Newport, 1991). All had been in the United States for approximately 10 years: Some had arrived in early childhood, others as adults. As [FIGURE 9.6](#) reveals, those who learned their second language early learned it best.

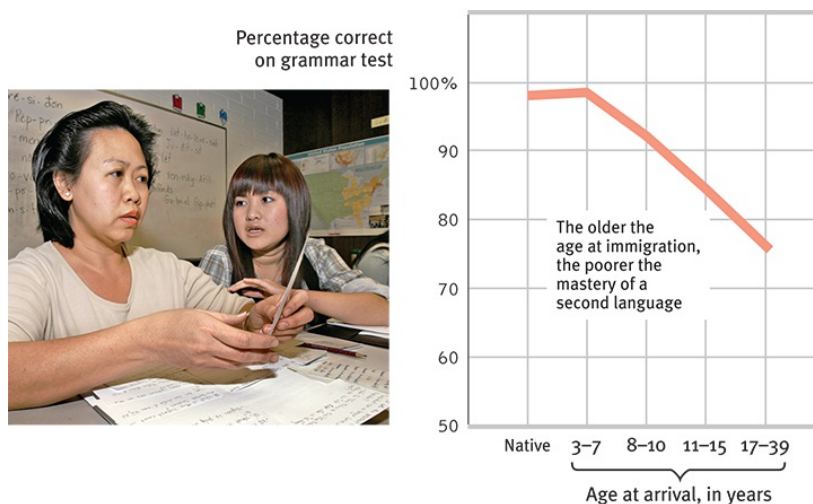

FIGURE 9.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Arizona Daily Star, A.E. Araiza/AP Photo; Data from Johnson & Newport, 1991

FIGURE 9.6 Our ability to learn a new language diminishes with age

Ten years after coming to the United States, Asian immigrants took an English grammar test. Although there is no sharply defined critical period for second language learning, those who arrived before age 8 understood American English grammar as well as native speakers did. Those who arrived later did not. (Data from Johnson & Newport, 1991.)

The older people are when moving to a new country, the harder it is to

learn its language and to absorb its culture (Cheung et al., 2011; Hakuta et al., 2003). Cognitive psychologist Stephen Kosslyn (2008) summed it up nicely: “Children can learn multiple languages without an accent and with good grammar, if they are exposed to the language before puberty. But after puberty, it’s very difficult to learn a second language so well. Similarly, when I first went to Japan, I was told not even to bother trying to bow, that there were something like a dozen different bows and I was always going to ‘bow with an accent.’”

“Childhood is the time for language, no doubt about it. Young children, the younger the better, are good at it; it is child’s play. It is a onetime gift to the species.”

Lewis Thomas, *The Fragile Species*, 1992

RETRIEVAL PRACTICE

RP-6 Why is it so difficult to learn a new language in adulthood?

ANSWER: Our brain’s *critical period* for language learning is in childhood, when we can absorb language structure almost effortlessly. As we move past that stage in our brain’s development, our ability to learn a new language diminishes dramatically.

Deafness and Language Development

The impact of early experiences is evident in language learning in prelingually (before learning language) deaf children born to hearing-nonsigning parents. These children typically do not experience language during their early years. Natively deaf children who learn sign language after age 9 never learn it as well as those who lose their hearing at age 9 after learning a spoken language such as English. They also never learn English as well as other natively deaf children who learned sign in infancy (Mayberry et al., 2002). Those who learn to sign as teens or adults are like immigrants who learn English after childhood: They can master basic words and learn to order

them, but they never become as fluent as native signers in producing and comprehending subtle grammatical differences (Newport, 1990). As a flower's growth will be stunted without nourishment, so, too, children will typically become linguistically stunted if isolated from language during the critical period for its acquisition.

More than 90 percent of all deaf children are born to hearing parents. Most of these parents want their children to experience their world of sound and talk. Cochlear implants enable this by converting sounds into electrical signals and stimulating the auditory nerve by means of electrodes threaded into the child's cochlea. But if an implant is to help children become proficient in oral communication, parents cannot delay the surgery until their child reaches the age of consent. Giving cochlear implants to children is hotly debated. Deaf culture advocates object to giving implants to children who were deaf prelingually. The National Association of the Deaf, for example, argues that deafness is *not* a disability because native signers are not linguistically disabled. More than five decades ago, Gallaudet University linguist William Stokoe (1960) showed that sign is a complete language with its own grammar, syntax, and meanings. Deaf culture advocates sometimes further contend that deafness could as well be considered "vision enhancement" as "hearing impairment." Close your eyes and immediately you, too, will notice your attention being drawn to your other senses. In one experiment, people who had spent 90 minutes sitting quietly blindfolded became more accurate in their location of sounds (Lewald, 2007). When kissing, lovers minimize distraction and increase sensitivity by closing their eyes.

People who lose one channel of sensation compensate with a slight enhancement of their other sensory abilities (Backman & Dixon, 1992; Levy & Langer, 1992). Those who have been deaf from birth exhibit enhanced visual processing (Almeida et al., 2015). Their auditory cortex, starved for sensory input, remains largely intact but becomes responsive to touch and to visual input (Karns et al., 2012). Once repurposed, the auditory cortex becomes less available for hearing—which helps explain why cochlear implants are most effective when given before age 2 (Geers & Nicholas, 2013; Niparko et al., 2010).

George Ancona

***Don't* means *Don't*—no matter how you say it!**

Deaf children of deaf-signing parents and hearing children of hearing parents have much in common. They develop language skills at about the same rate, and they are equally effective at opposing parental wishes and demanding their way.

LIVING IN A SILENT WORLD Worldwide, 360 million people live with hearing loss (WHO, 2013a). Some are profoundly deaf; most (more men than women) have hearing loss (Agrawal et al., 2008). Some were deaf from birth; others have known the hearing world. Some sign and identify with the language-based Deaf culture. Others, especially those who lost their hearing after speaking a language, are “oral” and converse with the hearing world by reading lips or written notes. Still others move between the two cultures.

The challenges of life without hearing may be greatest for children. Unable to communicate in customary ways, signing playmates may struggle to coordinate their play with speaking playmates. School achievement may also suffer; academic subjects are rooted in *spoken* languages. Adolescents may feel socially excluded, with a resulting low self-confidence. Deaf children who grow up around other deaf people more often identify with Deaf culture and feel positive self-esteem. If raised in a signing household, whether by deaf or hearing parents, they also express higher self-esteem and feel more accepted (Bat-Chava, 1993, 1994).

Adults who lose hearing late in life also face challenges. Expending effort to hear words drains their capacity to perceive, comprehend, and remember

them (Wingfield et al., 2005). In several studies, people with hearing loss, especially those not wearing hearing aids, have reported feeling sadder, being less socially engaged, and more often experiencing others' irritation (Chisolm et al., 2007; Fellingner et al., 2007; Kashubeck-West & Meyer, 2008; National Council on Aging, 1999). They also may experience a sort of shyness: "It's almost universal among the deaf to want to cause hearing people as little fuss as possible," observed Henry Kisor (1990, [p. 244](#)), a Chicago newspaper editor and columnist who lost his hearing at age 3. "We can be self-effacing and diffident to the point of invisibility. Sometimes this tendency can be crippling. I must fight it all the time." Helen Keller, both blind and deaf, noted that "blindness cuts people off from things. Deafness cuts people off from people."

I [DM] understand. My mother, with whom we communicated by writing notes on an erasable "magic pad," spent her last dozen years in an utterly silent world, largely withdrawn from the stress and strain of trying to interact with people outside a small circle of family and old friends. My own hearing is declining on a trajectory toward hers (with my hearing aids out at night, I cannot understand my wife speaking from her adjacent pillow). Even with hearing aids, I sit front and center at plays and meetings and seek quiet corners in restaurants. I do benefit from cool technology (see hearingloop.org) that, at the press of a button, can transform my hearing aids into in-the-ear loudspeakers for the broadcast of phone, TV, and public address system sound. Yet I still experience frustration when, with or without hearing aids, I can't hear the joke everyone else is guffawing over; when, after repeated tries, I just can't catch that exasperated person's question and can't fake my way around it; when family members give up and say, "Oh, never mind" after trying three times to tell me something unimportant.

Andy Richter/Aurora Photos

Hearing improved

A boy in Malawi experiences new hearing aids.

As she aged, my mother came to feel that seeking social interaction was simply not worth the effort. I share newspaper columnist Kisor’s belief that communication is worth the effort ([p. 246](#)): “So, . . . I will grit my teeth and plunge ahead.” To reach out, to connect, to communicate with others, even across a chasm of silence, is to affirm our humanity as social creatures.

The Brain and Language

LOQ 9-12 What brain areas are involved in language processing and speech?

We think of speaking and reading, or writing and reading, or singing and speaking as merely different examples of the same general ability—language. But consider this curious finding: Damage to any of several cortical areas can produce [aphasia](#), impairment of language. Even more curious, some people with aphasia can speak fluently but cannot read (despite good vision). Others can comprehend what they read but cannot speak. Still others can write but not read, read but not write, read numbers but not letters, or sing but not speak. These cases suggest that language is complex, and that different brain areas must serve different language functions.

aphasia impairment of language, usually caused by left hemisphere damage

either to Broca's area (impairing speaking) or to Wernicke's area (impairing understanding).

Indeed, in 1865, French physician Paul Broca confirmed a fellow physician's observation that after damage to an area of the left frontal lobe (later called **Broca's area**) a person would struggle to *speak* words, yet could sing familiar songs and comprehend speech. A decade later, German investigator Carl Wernicke discovered that after damage to a specific area of the left temporal lobe (**Wernicke's area**), people were unable to *understand* others' words and could speak only meaningless words. Asked to describe a picture that showed two boys stealing cookies behind a woman's back, one patient responded: "Mother is away her working her work to get her better, but when she's looking the two boys looking the other part. She's working another time" (Geschwind, 1979).

Broca's area helps control language expression—an area of the frontal lobe, usually in the left hemisphere, that directs the muscle movements involved in speech.

Wernicke's area a brain area involved in language comprehension and expression; usually in the left temporal lobe.

Today's neuroscience has confirmed brain activity in Broca's and Wernicke's areas during language processing (**FIGURE 9.7**). Among people with aphasia, electrical stimulation of Broca's area can help restore their speaking abilities (Marangolo et al., 2016). But we also now know that the brain's processing of language is complex. Broca's area coordinates the brain's processing of language in other areas as well (Flinker et al., 2015; Tremblay & Dick, 2016). Although you experience language as a single, unified stream, functional MRI scans would show that your brain is busily multitasking and networking. Different neural networks are activated by nouns and verbs (or objects and actions); by different vowels; by stories of visual versus motor experiences; by who spoke and what was said; and by many other stimuli (Perrachione et al., 2011; Shapiro et al., 2006; Speer et al., 2009). Moreover, if you're lucky enough to be natively fluent in two

languages, your brain processes them in similar areas, but in different areas if you learned a second language after the first (Berken et al., 2015). Bilingual spoken and signed language are also handled by different brain areas (Kovelman et al., 2014).

FIGURE 9.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 9.7 Brain activity when speaking and hearing words

The point to remember: In processing language, as in other forms of information processing, the brain operates by dividing its mental functions—speaking, perceiving, thinking, remembering—into subfunctions. Your conscious experience of reading this page *seems* indivisible, but many different neural networks are pooling their work to give the string of words coherence and meaning (Fedorenko et al., 2016). *E pluribus unum*: Out of many, one.

“It is the way systems interact and have a dynamic interdependence that is—unless one has lost all sense of wonder—quite awe-inspiring.”

Simon Conway Morris, “The Boyle Lecture,” 2005

RETRIEVAL PRACTICE

RP-7 _____ is one part of the brain that, if damaged, might impair your ability to speak words. Damage to _____ might impair your ability to understand language.

ANSWER: Broca's area; Wernicke's area

Do Other Species Have Language?

LOQ 9-13 What do we know about other species' capacity for language?

Humans have long and proudly proclaimed that language sets us above all other animals. “When we study human language,” asserted linguist Noam Chomsky (1972), “we are approaching what some might call the ‘human essence,’ the qualities of mind that are, so far as we know, unique [to humans].” Let’s see if research on animal language supports claims that humans, alone, have language.

Jim Cummins/Getty Images

Talking hands

Human language appears to have evolved from gestured communications (Corballis, 2002, 2003; Pollick & de Waal, 2007). Even today, gestures are naturally associated with spontaneous speech, and similarly so for blind and sighted speakers of a given language (Özçaliskan et al., 2016). Both gesture and speech communicate, and when they convey the same rather than different information (as they do in baseball’s sign language), we humans understand faster and more accurately (Hostetter, 2011; Kelly et al., 2010). Outfielder William Hoy, the first deaf player to join the major leagues (1892), reportedly helped invent hand signals for “Strike!” “Safe!” (shown here) and “Yerr out!” (Pollard, 1992). Referees in all sports now use invented signs, and fans are fluent in sports sign language.

Some animals display basic language processing. Pigeons can learn the difference between words and nonwords, but they could never read this book (Scarf et al., 2016). Other animals show impressive comprehension and communication. Various monkey species sound different alarm cries for different predators, such as a barking call for a leopard, a cough for an eagle, and a chattering for a snake. Hearing the leopard alarm, vervets climb the nearest tree. Hearing the eagle alarm, they rush into the bushes. Hearing the snake chatter, they stand up and scan the ground (Byrne, 1991; Clarke et al., 2015; Coye et al., 2015). To indicate such things as a type of threat—an eagle, a leopard, a falling tree, a neighboring group—monkeys will combine 6 different calls into a 25-call sequence (Balter, 2010). But are such communications language?

In the late 1960s, psychologists Allen Gardner and Beatrix Gardner (1969) aroused enormous scientific and public interest with their work with Washoe, a young chimpanzee. Building on chimpanzees' natural tendencies for gestured communication, they taught Washoe sign language. After four years, Washoe could use 132 signs; by her life's end in 2007, she was using 250 signs (Metzler, 2011; Sanz et al., 1998).

During the 1970s, more and more reports came in. Some chimpanzees were stringing signs together to form sentences. Washoe, for example, signed "You me go out, please." Some word combinations seemed creative—saying *water bird* for "swan" or *apple-which-is-orange* for "orange" (Patterson, 1978; Rumbaugh, 1977).

But by the late 1970s, other psychologists were growing skeptical. Were the chimps language champs or were the researchers chumps? Consider, said the skeptics:

- Ape vocabularies and sentences are simple, rather like those of a 2-year-old child. And apes gain their limited vocabularies only with great difficulty (Wynne, 2004, 2008). Speaking or signing children can easily soak up dozens of new words each week, and 60,000 by adulthood.
- Chimpanzees can make signs or push buttons in sequence to get a reward. But pigeons, too, can peck a sequence of keys to get grain (Straub et al., 1979). The apes' signing might be nothing more than aping their trainers' signs and learning that certain arm movements produce rewards (Terrace, 1979).

- When information is unclear, we are prone to *perceptual set*—a tendency to see what we want or expect to see. Interpreting chimpanzee signs as language may have been little more than the trainers’ wishful thinking (Terrace, 1979). When Washoe signed *water bird*, she may have been separately naming *water* and *bird*.
- “Give orange me give eat orange me eat orange . . .” is a far cry from the exquisite syntax of a 3-year-old (Anderson, C. A., 2004; Pinker, 1995). Rules of syntax in human language govern the order of words in sentences, so to a child, “You tickle” and “Tickle you” communicate different ideas. A chimpanzee, lacking these rules of syntax, might use the same sequence of signs for both phrases.

Controversy can stimulate progress, and in this case, it triggered more evidence of chimpanzees’ abilities to think and communicate. One surprising finding was that Washoe trained her adopted son Loulis to use the signs she had learned. After her second infant died, Washoe became withdrawn when told, “Baby dead, baby gone, baby finished.” Two weeks later, researcher-caretaker Roger Fouts (1992, 1997) signed better news: “I have baby for you.” Washoe reacted with instant excitement. Hair on end, she swaggered and panted while signing over and again, “Baby, my baby.” It took several hours for the foster mom and infant to warm to each other, but then Washoe broke the ice by signing, “Come baby” and cuddling Loulis. Without human assistance, Loulis eventually picked up 68 signs, simply by observing Washoe and three other language-trained chimps signing together.

Even more stunning was a later report: Kanzi, a bonobo with a reported 384-word vocabulary, could understand syntax in spoken English (Savage-Rumbaugh et al., 1993, 2009). Kanzi, who appears to have the receptive language ability of a human 2-year-old, has responded appropriately when asked, “Can you show me the light?” and “Can you bring me the [flash]light?” and “Can you turn the light on?” Given stuffed animals and asked—for the first time—to “make the dog bite the snake,” he put the snake to the dog’s mouth.

Susanne Baus/AFP/Getty Images/Newscom

Comprehending canine

Border collie Rico had a vocabulary of 200 human words. If asked to retrieve a toy with a name he had never heard, Rico would pick out a new toy from a group of familiar items (Kaminski et al., 2004). Hearing that name for the second time four weeks later, Rico more often than not would retrieve the same toy. Another border collie, Chaser, has set an animal record by learning more than 1000 object names (Pilley, 2013). Like a 3-year-old child, she can also categorize them by function and shape. She can “fetch a ball” or “fetch a doll.”

So, how should we interpret such studies? Are humans the only language-using species? If by language we mean an ability to communicate through a meaningful sequence of symbols, then apes are indeed capable of language. But if we mean a verbal or signed expression of complex grammar, most psychologists would now agree that humans alone possess language. Moreover, 2¹/₂-year-old children display some cognitive abilities, such as following an actor’s gaze to a target, that are unmatched even by chimpanzees (Herrmann et al., 2010). Humans, alone, also have a version of a gene (*FOXP2*) that helps enable the lip, tongue, and vocal cord movements

of human speech (Lieberman, 2013). Humans with a mutated form of this gene have difficulty speaking words.

One thing is certain: Studies of animal language and thinking have moved psychologists toward a greater appreciation of other species' remarkable abilities (Friend, 2004; Rumbaugh & Washburn, 2003; Wilson et al., 2015). In the past, many psychologists doubted that other species could plan, form concepts, count, use tools, or show compassion (Thorpe, 1974). Today, thanks to animal researchers, we know better. Other species exhibit insight, show family loyalty, communicate with and care for one another, and transmit cultural patterns across generations. Working out what this means for the moral rights of other animals is an unfinished task.

Paul Fusco/Magnum

But is this language?

Chimpanzees' ability to express themselves in American Sign Language (ASL) raises questions about the very nature of language. Here, the trainer is asking, "What is this?" The sign in response is "Baby." Does the response constitute language?

RETRIEVAL PRACTICE

RP-8 If your dog barks at a stranger at the door, does this qualify as language? What if the dog yips in a telltale way to let you know she needs to go out?

ANSWER: These are definitely communications. But if language consists of words and the grammatical rules we use to combine them to communicate meaning, few scientists would label a dog's barking and yipping as language.

For examples of intelligent communication and problem solving among orangutans, elephants, and killer whales, see the 6-minute **Video: How Intelligent Are Animals?** See also **Video: Case Studies** for a helpful tutorial animation on this type of research method.

Thinking and Language

LOQ 9-14 What is the relationship between thinking and language, and what is the value of thinking in images?

Thinking and language—which comes first? This is one of psychology’s great chicken-and-egg questions. Do our ideas come first and then the words to name them? Or are our thoughts conceived in words and unthinkable without them?

Linguist Benjamin Lee Whorf (1956) contended that “language itself shapes a [person’s] basic ideas.” The Hopi, who have no past tense for their verbs, could not readily *think* about the past, he said. Whorf’s **linguistic determinism** hypothesis is too extreme. We all think about things for which we have no words. (Can you think of a shade of blue you cannot name?) And we routinely have *unsymbolized* (wordless, imageless) thoughts, as when someone, while watching two men carry a load of bricks, wondered whether the men would drop them (Heavey & Hurlburt, 2008; Hurlburt et al., 2013).

linguistic determinism Whorf’s hypothesis that language determines the way we think.

Nevertheless, a weaker version of linguistic determinism—*linguistic relativism*—rightly emphasizes that our words influence our thinking (Gentner, 2016). To those who speak two dissimilar languages, such as English and Japanese, it seems obvious that a person may think differently in different languages (Brown, 1986). Unlike English, which has a rich vocabulary for self-focused emotions such as anger, Japanese has more words for interpersonal emotions such as sympathy (Markus & Kitayama, 1991). Many bilingual individuals report that they have different senses of self—that

they feel like different people—depending on which language they are using (Matsumoto, 1994; Pavlenko, 2014). In one series of studies with bilingual Israeli Arabs (who spoke both Arabic and Hebrew), participants thought differently about their social world, with differing automatic associations with Arabs and Jews, depending on which language the testing session used (Danziger & Ward, 2010). Depending on which emotion they want to express, bilingual people often switch languages. “When my mom gets angry at me, she’ll speak in Mandarin,” explained one Chinese-American student. “If she’s really mad, she’ll switch to Cantonese” (Chen et al., 2012). Bilingual individuals may even reveal different personality profiles when taking the same test in two languages, with their differing cultural associations (Chen & Bond, 2010; Dinges & Hull, 1992). When China-born, bilingual University of Waterloo students were asked to describe themselves in English, their responses fit typical Canadian profiles, expressing mostly positive self-statements and moods. When responding in Chinese, the same students gave typically Chinese self-descriptions, reporting more agreement with Chinese values and roughly equal positive and negative self-statements and moods (Ross et al., 2002). Similar attitude and personality changes have been shown when bicultural, bilingual people shift between the cultural frames associated with Spanish and English, or Arabic and English (Ogunnaike et al., 2010; Ramírez-Esparza et al., 2006). When responding in their second language, bilingual people’s moral judgments reflect less emotion—they respond with more “head” than “heart” (Costa et al., 2014). “Learn a new language and get a new soul,” says a Czech proverb.

So our words do influence our thinking (Boroditsky, 2011). Words define our mental categories. In Brazil, the isolated Piraha people have words for the numbers 1 and 2, but numbers above that are simply “many.” Thus, if shown 7 nuts in a row, they find it difficult to lay out the same number from their own pile (Gordon, 2004).

Prisma Bildagentur AG/Alamy

Culture and color

In Papua New Guinea, Berinmo children have words for different shades of “yellow,” which might enable them to spot and recall yellow variations more quickly. Here and everywhere, “the languages we speak profoundly shape the way we think, the way we see the world, the way we live our lives,” noted psychologist Lera Boroditsky (2009).

Words also influence our thinking about colors. Whether we live in New Mexico, New South Wales, or New Guinea, we *see* colors much the same, but we use our native language to *classify* and *remember* them (Davidoff, 2004; Roberson et al., 2004, 2005). Imagine viewing three colors and calling two of them “yellow” and one of them “blue.” Later you would likely see and recall the yellows as being more similar. But if you speak the language of Papua New Guinea’s Berinmo tribe, which has words for two different shades of yellow, you would more speedily perceive and better recall the variations between the two yellows. And if your language is Russian, which has distinct names for various shades of blue, such as *goluboy* and *siniy*, you might recall the yellows as more similar and remember the blues better. Words matter.

Perceived differences grow as we assign different names. On the color spectrum, blue blends into green—until we draw a dividing line between the portions we call “blue” and “green.” Although equally different on the color spectrum, two different items that share the same color name (as the two “blues” do in [FIGURE 9.8](#), contrast B) are harder to distinguish than two items

with different names (“blue” and “green,” as in [Figure 9.8](#), contrast A) (Özgen, 2004). Likewise, two places seem closer and more vulnerable to the same natural disaster if labeled as in the same state rather than at an equal distance in adjacent states (Burris & Branscombe, 2005; Mishra & Mishra, 2010). Tornadoes don’t know about state lines, but people do.

FIGURE 9.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 9.8 Language and perception

When people view blocks of equally different colors, they perceive those with different names as more different. Thus the “green” and “blue” in contrast A may appear to differ more than the two equally different blues in contrast B (Özgen, 2004).

Given words’ subtle influence on thinking, we do well to choose our words carefully. Is “A child learns language as *he* interacts with *his* caregivers” any different from “Children learn language as *they* interact with *their* caregivers”? Many studies have found that it is. When hearing the generic *he* (as in “the artist and his work”) people are more likely to picture a male (Henley, 1989; Ng, 1990). If *he* and *his* were truly gender free, we shouldn’t skip a beat when hearing that “man, like other mammals, nurses his young.”

To expand language is to expand the ability to think. Young children’s thinking develops hand in hand with their language (Gopnik & Meltzoff, 1986). Indeed, it is very difficult to think about or conceptualize certain abstract ideas (*commitment*, *freedom*, or *rhyming*) without language. And what is true for preschoolers is true for everyone: It *pays to increase your word power*. That’s why most textbooks, including this one, introduce new words—to teach new ideas and new ways of thinking. And that’s also why psychologist Steven Pinker (2007) titled his book on language *The Stuff of Thought*.

“All words are pegs to hang ideas on.”

Henry Ward Beecher, *Proverbs from Plymouth Pulpit*, 1887

Increased word power helps explain what McGill University researcher Wallace Lambert has called the *bilingual advantage* (Lambert, 1992; Lambert et al., 1993). In some studies (though not all) bilingual people have exhibited skill at inhibiting one language while using the other—for example, inhibiting “crayón amarillo” from home speech while saying “yellow crayon” at school (Bialystok et al., 2015; de Bruin et al., 2015a,b). And thanks to their well-practiced “executive control” over language, they also more readily inhibit their attention to irrelevant information (Barac et al., 2016; Kroll & Bialystok, 2013). This superior attentional control is evident from 7 months of age into adulthood and even helps protect against cognitive decline in later life (Bak et al., 2014; Bialystok et al., 2012; Kroll et al., 2014). Bilingual children also exhibit enhanced social skill, by being better able to shift to understand another’s perspective (Fan et al., 2015).

Bilingual people’s switching between different languages does, however, take a moment (Kleinman & Gollan, 2016; Palomar-García et al., 2015). That’s a phenomenon I [DM] failed to realize before speaking to bilingual Chinese colleagues in Beijing. While I spoke in English, my accompanying slides were in Chinese. Alas, I later learned, the translated slides required constant “code switching” from my spoken words, thus making it *hard* for my audience to process both.

Consider how researchers have learned about the benefits of learning more than one language by engaging online with **Immersive Learning: How Would You Know If There Is a Bilingual Advantage?**

Lambert helped devise a Canadian program that has, since 1981, immersed millions of English-speaking children in French (Statistics Canada, 2013). Not surprisingly, the children attain a natural French fluency unrivaled by other methods of language teaching. Moreover, compared with similarly capable children in control groups, they do so without detriment to their English fluency, and with increased aptitude scores, creativity, and appreciation for French-Canadian culture (Genesee & Gándara, 1999; Lazaruk, 2007).

Whether we are in the linguistic minority or majority, language links us to

one another. Language also connects us to the past and the future. “To destroy a people,” goes a saying, “destroy their language.”

RETRIEVAL PRACTICE

RP-9 Benjamin Lee Whorf’s controversial hypothesis, called _____, suggested that we cannot think about things unless we have words for those concepts or ideas.

ANSWER: linguistic determinism

Thinking in Images

When you are alone, do you talk to yourself? Is “thinking” simply conversing with yourself? Words do convey ideas. But sometimes ideas precede words. To turn on the cold water in your bathroom, in which direction do you turn the handle? To answer, you probably thought not in words but with *implicit* (nondeclarative, procedural) memory—a mental picture of how you do it.

Indeed, we often think in images. Artists think in images. So do composers, poets, mathematicians, athletes, and scientists. Albert Einstein reported that he achieved some of his greatest insights through visual images and later put them into words. Pianist Liu Chi Kung harnessed the power of thinking in images. One year after placing second in the 1958 Tchaikovsky piano competition, Liu was imprisoned during China’s cultural revolution. Soon after his release, after seven years without touching a piano, he was back on tour. Critics judged Liu’s musicianship as better than ever. How did he continue to develop without practice? “I did practice,” said Liu, “every day. I rehearsed every piece I had ever played, note by note, in my mind” (Garfield, 1986).

“When we see a person walking down the street talking to himself, we generally assume that he is mentally ill. But we all talk to ourselves continuously—we just have the good sense of keeping our mouths shut. . . . It’s as though we are having a conversation with an imaginary friend possessed of infinite patience. Who are we talking to?”

Sam Harris, “We Are Lost in Thought,” 2011

For someone who has learned a skill, such as ballet dancing, even *watching* the activity will activate the brain’s internal simulation of it, reported one British research team (Calvo-Merino et al., 2004). So, too, will *imagining* a physical experience, which activates some of the same neural networks that are active during the actual experience (Grèzes & Decety, 2001). Small wonder, then, that mental practice has become a standard part of training for Olympic athletes (Blumenstein & Orbach, 2012; Ungerleider, 2005).

Blend Images/Getty Images

One experiment on mental practice and basketball free-throw shooting tracked the University of Tennessee women’s team over 35 games (Savoy & Beitel, 1996). During that time, the team’s free-throw accuracy increased from approximately 52 percent in games following standard physical

practice, to some 65 percent after mental practice. Players had repeatedly imagined making free throws under various conditions, including being “trash-talked” by their opposition. In a dramatic conclusion, Tennessee won the national championship game in overtime, thanks in part to their free-throw shooting.

Mental rehearsal can also help you achieve an academic goal, as researchers demonstrated with two groups of introductory psychology students facing a midterm exam one week later (Taylor et al., 1998). (Students who were not engaged in any mental rehearsal formed a control group.) The first group spent five minutes each day visualizing themselves scanning the posted grade list, seeing their A, beaming with joy, and feeling proud. This daily *outcome simulation* had little effect, adding only 2 points to their exam-score average. The second group spent five minutes each day visualizing themselves effectively studying—reading their text, going over notes, eliminating distractions, declining an offer to go out. This daily *process simulation* paid off: The group began studying sooner, spent more time at it, and beat the others’ average score by 8 points. *The point to remember*: It’s better to spend your fantasy time planning *how* to reach your goal than to focus on your desired destination.

To experience your own thinking as (a) manipulating words and (b) manipulating images, see **PsychSim 6: My Head Is Spinning!**

* * *

What, then, should we say about the relationship between thinking and language? As we have seen, language influences our thinking. But if thinking did not also affect language, there would never be any new words. And new words and new combinations of old words express new ideas. The basketball term *slam dunk* was coined after the act itself had become fairly common. *Blogs* became part of our language after web logs appeared. So, let us say that *thinking affects our language, which then affects our thought* ([FIGURE 9.9](#)).

FIGURE 9.9 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Jupiterimages/Getty Images

FIGURE 9.9 The interplay of thought and language

The traffic runs both ways between thinking and language. Thinking affects our language, which affects our thought.

Psychological research on thinking and language mirrors the mixed impressions of our species by those in fields such as literature and religion. The human mind is simultaneously capable of striking intellectual failures and of striking intellectual power. Misjudgments are common and can have disastrous consequences. So we do well to appreciate our capacity for error. Yet our ingenuity at problem solving and our extraordinary power of language mark humankind as almost “infinite in faculties.”

RETRIEVAL PRACTICE

RP-10 What is mental practice, and how can it help you to prepare for an upcoming event?

ANSWER: Mental practice uses visual imagery to mentally rehearse future behaviors, activating some of the same brain areas used during the actual behaviors. Visualizing the details of the process is more effective than visualizing only your end goal.

What time is it now? When we asked you (in the section on overconfidence) to estimate how quickly you would finish this chapter, did you underestimate or overestimate?

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Children reach the one-word stage of speech development at about

- a. 4 months.
- b. 6 months.
- c. 1 year.
- d. 2 years.

The three basic building blocks of language are _____, _____, and _____.

When young children speak in short phrases using mostly verbs and nouns, this is referred to as _____.

According to Chomsky, all languages share a(n) _____.

Most researchers agree that apes can

- a. communicate through symbols.
- b. reproduce most human speech sounds.
- c. master language in adulthood.
- d. surpass a human 3-year-old in language skills.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Group Differences in Intelligence Test Scores

Three huge controversies have sparked debate in and beyond psychology. First is the “memory war,” over whether traumatic experiences are repressed and can later be recovered, with therapeutic benefit. Second is the “gender war,” over the extent to which nature and nurture shape our behaviors as men and women. In this chapter, we meet the third great controversy, the “intelligence war”: Does each of us have an inborn general mental capacity (intelligence)? Can we quantify this capacity as a meaningful number? And can we measure intelligence without bias?

School boards, courts, and scientists debate the use and fairness of tests that assess people’s mental abilities and assign them a score. Is intelligence testing a constructive way to guide people toward suitable opportunities? Or is it a potent, discriminatory weapon camouflaged as science? First, some basic questions:

- What is intelligence?
- How can we best assess intelligence?
- How does intelligence change over time and vary among individuals?
- How do heredity and experience together weave the intelligence fabric?
- What intelligence test score similarities and differences exist among groups, and what accounts for those differences? Should we use such differences to rank people? To admit them to colleges or universities? To hire them?

This chapter offers answers, by identifying a variety of mental gifts and concluding that the recipe for high achievement blends talent and grit.

What Is Intelligence?

LOQ

LEARNING OBJECTIVE QUESTION

10-1

How do psychologists define *intelligence*, and what are the arguments for *g*?

In many studies, *intelligence* has been defined as whatever *intelligence tests* measure, which has tended to be school smarts. But intelligence is not a quality like height or weight, which has the same meaning to everyone worldwide. People assign this term to the qualities that enable success in their own time and culture (Sternberg & Kaufman, 1998). In Cameroon's equatorial forest, *intelligence* may reflect understanding the medicinal qualities of local plants. In a North American high school, it may reflect mastering difficult concepts in calculus or chemistry. In both places, [intelligence](#) is the ability to learn from experience, solve problems, and use knowledge to adapt to new situations.

intelligence the ability to learn from experience, solve problems, and use knowledge to adapt to new situations.

You probably know some people with talents in science, others who excel in the humanities, and still others gifted in athletics, art, music, or dance. You may also know a talented artist who is stumped by the simplest math problem, or a brilliant math student who struggles when discussing literature. Are all these people intelligent? Could you rate their intelligence on a single scale? Or would you need several different scales?

© imagebroker/Alamy

Hands-on healing

The socially constructed concept of intelligence varies from culture to culture. This natural healer in Cameroon displays intelligence in his knowledge about medicinal plants and his understanding of the needs of the people he is helping.

Is Intelligence One General Ability?

Charles Spearman (1863–1945) believed we have one [general intelligence](#) (often shortened to *g*) that is at the heart of all our intelligent behavior, from navigating the sea to excelling in school. He granted that people often have special, outstanding abilities. But he noted that those who score high in one area, such as verbal intelligence, typically score higher than average in other areas, such as spatial or reasoning ability. Spearman's belief stemmed in part from his work with *factor analysis*, a statistical procedure that identifies clusters of related items.

general intelligence (*g*) according to Spearman and others, underlies all mental abilities and is therefore measured by every task on an intelligence test.

This idea of a general mental capacity expressed by a single intelligence score was controversial in Spearman's day, and so it remains. One of Spearman's early opponents was L. L. Thurstone (1887–1955). Thurstone gave 56 different tests to people and mathematically identified seven clusters of *primary mental abilities* (word fluency, verbal comprehension, spatial ability, perceptual speed, numerical ability, inductive reasoning, and memory). Thurstone did not rank people on a single scale of general aptitude. But when other investigators studied these profiles, they detected a persistent tendency: Those who excelled in one of the seven clusters generally scored well on the others. So, the investigators concluded, there was still some evidence of a *g* factor.

We might, then, liken mental abilities to physical abilities: The ability to run fast is distinct from the eye-hand coordination required to throw a ball on target. Yet there remains some tendency for good things to come packaged together—for running speed and throwing accuracy to correlate. So, too, with intelligence. Several distinct abilities tend to cluster together and to correlate enough to define a general intelligence factor. Distinct brain networks enable distinct abilities, with *g* explained by their coordinated activity (Cole et al., 2015; Hampshire et al., 2012). The result is a chorus of actions orchestrated through the best possible distribution of mental resources (Carroll & Bright, 2016; Lee et al., 2015).

“*g* is one of the most reliable and valid measures in the behavioral domain . . . and it predicts important social outcomes such as educational and occupational levels far better than any other trait.”

Behavior geneticist Robert Plomin (1999)

Theories of Multiple Intelligences

LOQ 10-2 How do Gardner's and Sternberg's theories of multiple

intelligences differ, and what criticisms have they faced?

Other psychologists, particularly since the mid-1980s, have sought to extend the definition of *intelligence* beyond the idea of academic smarts.

Gardner's Multiple Intelligences

Howard Gardner has identified eight *relatively independent intelligences*, including the verbal and mathematical aptitudes assessed by standardized tests ([FIGURE 10.1](#)). Thus, the computer programmer, the poet, the street-smart adolescent, and the basketball team's play-making point guard exhibit different kinds of intelligence (Gardner, 1998). Gardner (1999a) has also proposed a ninth possible intelligence—*existential intelligence*—the ability “to ponder large questions about life, death, existence.”

FIGURE 10.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.1 Gardner's eight intelligences

Gardner has also proposed existential intelligence (the ability to ponder deep questions about life) as a ninth possible intelligence.

Gardner (1983, 2006; 2011; Davis et al., 2011) views these intelligence domains as multiple abilities that come in different packages. Brain damage, for example, may destroy one ability but leave others intact. And consider people with [savant syndrome](#), who have an island of brilliance but often score low on intelligence tests and may have limited or no language ability

(Treffert, 2010). Some can compute complicated calculations almost instantly, or identify the day of the week of any given historical date, or render incredible works of art or music (Miller, 1999).

savant syndrome a condition in which a person otherwise limited in mental ability has an exceptional specific skill, such as in computation or drawing.

About 4 in 5 people with savant syndrome are male, and many also have *autism spectrum disorder (ASD)*, a developmental disorder. The late memory whiz Kim Peek (who did not have ASD) inspired the movie *Rain Man*. It took him 8 to 10 seconds to read and remember a page. During his lifetime, he memorized 9000 books, including Shakespeare's works and the Bible. He could provide GPS-like travel directions within any major U.S. city. Yet he could not button his clothes, and he had little capacity for abstract concepts. Asked by his father at a restaurant to lower his voice, he slid down in his chair to lower his voice box. Asked for Lincoln's Gettysburg Address, he responded, "227 North West Front Street. But he only stayed there one night—he gave the speech the next day" (Treffert & Christensen, 2005).

To witness extraordinary savant ability in music, see the **Video: Savant Musical Skills**.

Then Chih Wey/Newscom/Xinhua News Agency/Singapore/

Islands of genius: Savant syndrome

After a brief helicopter ride over Singapore followed by five days of drawing, British savant artist Stephen Wiltshire accurately reproduced an aerial view of the city from memory.

Sternberg's Three Intelligences

Robert Sternberg (1985, 2011) agrees with Gardner that there is more to success than traditional intelligence and that we have multiple intelligences. But Sternberg's *triarchic theory* proposes three, not eight or nine, intelligences:

- *Analytical (academic problem-solving) intelligence* is assessed by intelligence tests, which present well-defined problems having a single right answer. Such tests predict school grades reasonably well and vocational success more modestly.

“You have to be careful, if you’re good at something, to make sure you don’t think you’re good at other things that you aren’t necessarily so good at. . . . Because I’ve been very successful at [software development] people come in and expect that I have wisdom about topics that I don’t.”

Philanthropist Bill Gates (1998)

- ***Creative intelligence*** is demonstrated in innovative smarts: the ability to adapt to new situations and generate novel ideas.
- ***Practical intelligence*** is required for everyday tasks that may be poorly defined and may have multiple solutions.

Donald Reilly The New Yorker Collection/
The Cartoon Bank

"You're wise, but you lack tree smarts."

With support from the U.S. College Board (which administers the widely used SAT Reasoning Test to U.S. college and university applicants), Sternberg (2015) and his collaborators have developed new measures of creativity (such as thinking up a caption for an untitled cartoon) and practical thinking (such as figuring out how to move a large bed up a winding staircase). Compared with older measures, these more comprehensive assessments improve prediction of American students' first-year college grades.

Gardner and Sternberg differ in some areas, but they agree on two important points: Multiple abilities can contribute to life success, and differing varieties of giftedness bring both spice to life and challenges for education. Trained to appreciate such variety, many teachers have applied multiple intelligence theories in their classrooms.

Criticisms of Multiple Intelligence Theories

Wouldn't it be nice if the world were so fair that a weakness in one area would be compensated by genius in another? Alas, say critics, the world is not fair (Ferguson, 2009; Scarr, 1989). Research using factor analysis confirms that there is a general intelligence factor: *g* matters (Johnson et al., 2008). It predicts performance on various complex tasks and in various jobs (Gottfredson, 2002a,b, 2003a,b; see also [FIGURE 10.2](#)). And extremely high cognitive ability scores predict exceptional achievements, such as doctoral degrees and publications (Kuncel & Hezlett, 2010).

FIGURE 10.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.2 Smart and rich?

Jay Zagorsky (2007) tracked 7403 participants in the U.S. National Longitudinal Survey of Youth across 25 years. As shown in this illustrative scatterplot, their intelligence scores correlated $+ .30$, a moderate positive correlation, with their later income.

Even so, “success” is not a one-ingredient recipe. High intelligence may help you get into a profession (via schools and training programs), but it won’t make you successful once there. Success is a combination of talent and *grit*: Those who become highly successful tend also to be conscientious, well-connected, and doggedly energetic. K. Anders Ericsson and others report a *10-year rule*: A common ingredient of expert performance in chess, dance, sports, computer programming, music, and medicine is “about 10 years of intense, daily practice” (Ericsson, 2007; Ericsson & Pool, 2016; Simon & Chase, 1973). Becoming a professional musician or an elite athlete requires, first, native ability (Macnamara et al., 2014, 2016). But it also requires years of practice—about 11,000 hours on average, and a *minimum* of 3000 hours (Campitelli & Gobet, 2011). The recipe for success is a gift of nature plus a whole lot of nurture.

Spatial intelligence genius

In 1998, World Checkers Champion Ron “Suki” King of Barbados set a new record by simultaneously playing 385 players in 3 hours and 44 minutes. Thus, while his opponents often had hours to plot their game moves, King could only devote about 35 seconds to each game. Yet he still managed to win all 385 games!

RETRIEVAL PRACTICE

RP-1 How does the existence of savant syndrome support Gardner’s theory of multiple intelligences?

ANSWER: People with savant syndrome have limited mental ability overall but possess one or more exceptional skills. According to Howard Gardner, this suggests that our abilities come in separate packages rather than being fully expressed by one general intelligence that encompasses all our talents.

For more on how self-disciplined grit feeds achievement, see [Chapter 11](#).

Emotional Intelligence

LOQ 10-3 What are the four components of emotional intelligence?

Some psychologists have further explored our *social intelligence*—the know-how involved in understanding social situations and managing ourselves successfully (Cantor & Kihlstrom, 1987). Psychologist Edward Thorndike first proposed the concept in 1920, noting that “the best mechanic in a factory may fail as a foreman for lack of social intelligence” (Goleman, 2006, [p. 83](#)).

A critical part of social intelligence, [emotional intelligence](#), consists of four abilities (Mayer et al., 2002, 2011, 2012):

emotional intelligence the ability to perceive, understand, manage, and use emotions.
--

- *Perceiving* emotions (recognizing them in faces, music, and stories)
- *Understanding* emotions (predicting them and how they may change and blend)
- *Managing* emotions (knowing how to express them in varied situations)
- *Using* emotions to enable adaptive or creative thinking

Emotionally intelligent people are both socially aware and self-aware. They avoid being hijacked by overwhelming depression, anxiety, or anger. They can read others' emotional cues and know what to say to soothe a grieving friend, encourage a workmate, and manage a conflict. They can delay gratification in pursuit of long-range rewards. Thus, emotionally intelligent people more often succeed in relationship, career, and parenting situations than do academically smarter but less emotionally intelligent people (Cherniss, 2010a,b; Czarna et al., 2016; Miao et al., 2016). They also tend to be happy and healthy (Sánchez-Álvarez et al., 2016; Schutte et al., 2007, 2016). Aware of these benefits, school-based programs have sought to increase teachers' and students' emotional intelligence (Nathanson et al., 2016).

Some scholars, however, are concerned that emotional intelligence stretches the intelligence concept too far (Visser et al., 2006). Howard Gardner (1999b) includes interpersonal and intrapersonal intelligences as two of his multiple intelligences. But he notes that we should respect emotional sensitivity, creativity, and motivation as important but different. Stretch *intelligence* to include everything we prize and the word will lose its meaning.

* * *

For a summary of these theories of intelligence, see [TABLE 10.1](#).

TABLE 10.1
Comparing Theories of Intelligence

Theory	Summary	Strengths	Other Considerations
<i>Spearman's</i>	A basic intelligence	Different abilities,	Human abilities

<i>general intelligence (g)</i>	predicts our abilities in varied academic areas.	such as verbal and spatial, do have some tendency to correlate.	are too diverse to be encapsulated by a single general intelligence factor.
<i>Thurstone's primary mental abilities</i>	Our intelligence may be broken down into seven distinct factors.	A single <i>g</i> score is not as informative as scores for seven primary mental abilities.	Even Thurstone's seven mental abilities show a tendency to cluster, suggesting an underlying <i>g</i> factor.
<i>Gardner's multiple intelligences</i>	Our abilities are best classified into eight or nine independent intelligences, which include a broad range of skills beyond traditional school smarts.	Intelligence is more than just verbal and mathematical skills. Other abilities are equally important to our human adaptability.	Should all our abilities be considered <i>intelligences</i> ? Shouldn't some be called less vital <i>talents</i> ?
<i>Sternberg's triarchic theory</i>	Our intelligence is best classified into three areas that predict real-world success: analytical, creative, and practical.	These three domains can be reliably measured.	These three domains may be less independent than Sternberg thought and may actually share an underlying <i>g</i> factor.
<i>Emotional intelligence</i>	Social intelligence is an important indicator of life success. Emotional intelligence is a key aspect, consisting of perceiving, understanding, managing, and using emotions.	These four components predict social success and emotional well-being.	Does this stretch the concept of intelligence too far?

The procrastinator's motto: "Hard work pays off later; laziness pays off now."

Assessing Intelligence

LOQ 10-4 What is an intelligence test, and how do achievement and aptitude tests differ?

An [intelligence test](#) assesses people's mental aptitudes and compares them with those of others, using numerical scores. How do we design such tests, and what makes them credible? Consider why psychologists created tests of mental abilities and how they have used them.

intelligence test a method for assessing an individual's mental aptitudes and comparing them with those of others, using numerical scores.

By this point in your life, you've faced dozens of ability tests: school tests of basic reading and math skills, course exams, intelligence tests, driver's license exams. Psychologists classify such tests as either [achievement tests](#), intended to *reflect* what you have learned, or [aptitude tests](#), intended to *predict* your ability to learn a new skill. Exams covering what you have learned in this course are achievement tests. A college entrance exam, which seeks to predict your ability to do college work, is an aptitude test—a “thinly disguised intelligence test,” says Howard Gardner (1999b). Indeed, report Meredith Frey and Douglas Detterman (2004), total scores on the U.S. SAT have correlated +0.82 with general intelligence test scores in a national sample of 14- to 21-year-olds ([FIGURE 10.3](#)).

achievement test a test designed to assess what a person has learned.

aptitude test a test designed to predict a person's future performance; *aptitude* is the capacity to learn.

Early and Modern Tests of Mental Abilities

LOQ 10-5 When and why were intelligence tests created, and how do today's tests differ from early intelligence tests?

Some societies emphasize the collective welfare of the family, community, and society. Other societies focus on promoting individual opportunity. Plato, a pioneer of the individualist tradition, wrote more than 2000 years ago in *The Republic* that “no two persons are born exactly alike; but each differs from the other in natural endowments, one being suited for one occupation and the other for another.” As heirs to Plato’s individualism, people in Western societies have pondered how and why individuals differ in mental ability.

Francis Galton: Presuming Hereditary Genius

Western attempts to assess such differences began in earnest with English scientist Francis Galton (1822–1911), who was fascinated with measuring human traits. When his cousin Charles Darwin proposed that nature selects successful traits through the survival of the fittest, Galton wondered if it might be possible to measure “natural ability” and to encourage those of high

ability to mate with one another. At the 1884 London Health Exhibition, more than 10,000 visitors received his assessment of their “intellectual strengths” based on such things as reaction time, sensory acuity, muscular power, and body proportions. But alas, on these measures, well-regarded adults and students did not outscore others. Nor did the measures correlate with each other.

Although Galton’s quest for a simple intelligence measure failed, he gave us some statistical techniques that we still use (as well as the phrase *nature and nurture*). And his persistent belief in the inheritance of genius—reflected in his book, *Hereditary Genius*—illustrates an important lesson from both the history of intelligence research and the history of science: Although science itself strives for objectivity, individual scientists are affected by their own assumptions and attitudes.

Alfred Binet: Predicting School Achievement

Modern intelligence testing traces its birth to early twentieth-century France, where a new law required all children to attend school. French officials knew that some children, including many newcomers to Paris, would struggle and need special classes. But how could the schools make fair judgments about children’s learning potential? Teachers might assess children who had little prior education as slow learners. Or they might sort children into classes by their social backgrounds. To minimize such bias, France’s minister of public education gave psychologist Alfred Binet the task of designing fair tests.

Binet and his student, Théodore Simon, began by assuming that all children follow the same course of intellectual development but that some develop more rapidly (Nicolas & Levine, 2012). A “dull” child should score much like a typical younger child, and a “bright” child like a typical older child. Thus, their goal became measuring each child’s **mental age**, the level of performance typically associated with a certain chronological age. The average 9-year-old, then, has a mental age of 9. Children with below-average mental ages, such as 9-year-olds who perform at the level of typical 7-year-olds, would struggle with age-appropriate schoolwork.

mental age a measure of intelligence test performance devised by Binet; the level of performance typically associated with children of a certain chronological

age. Thus, a child who does as well as an average 8-year-old is said to have a mental age of 8.

To measure mental age, Binet and Simon theorized that mental aptitude, like athletic aptitude, is a general capacity that shows up in various ways. They tested a variety of reasoning and problem-solving questions on Binet's two daughters, and then on "bright" and "backward" Parisian schoolchildren. Items answered correctly could then predict how well other French children would handle their schoolwork.

Binet and Simon made no assumptions concerning *why* a particular child was slow, average, or precocious. Binet personally leaned toward an environmental explanation. To raise the capacities of low-scoring children, he recommended "mental orthopedics" that would help develop their attention span and self-discipline. He believed his intelligence test did not measure inborn intelligence as a scale measures weight. Rather, it had a single practical purpose: to identify French schoolchildren needing special attention. Binet hoped his test would be used to improve children's education, but he also feared it would be used to label children and limit their opportunities (Gould, 1981).

Binet, 1909, p. 141

Alfred Binet (1857–1911)

"Some recent philosophers have given their moral approval to the

deplorable verdict that an individual's intelligence is a fixed quantity, one which cannot be augmented. We must protest and act against this brutal pessimism" (Binet, 1909, [p. 141](#)).

"The IQ test was invented to predict academic performance, nothing else. If we wanted something that would predict life success, we'd have to invent another test completely."

Social psychologist Robert Zajonc (1984b)

RETRIEVAL PRACTICE

RP-2 What did Binet hope to achieve by establishing a child's mental age?

ANSWER: Binet hoped that determining the child's mental age (the age that typically corresponds to a certain level of performance) would help identify appropriate school placements.

Lewis Terman: Measuring Innate Intelligence

Binet's fears were realized soon after his death in 1911, when others adapted his tests for use as a numerical measure of inherited intelligence. Stanford University professor Lewis Terman (1877–1956) tried the Paris-developed questions and age norms with California schoolchildren. But the French norms didn't work with California kids. Adapting some of Binet's original items, adding others, and establishing new age norms, Terman extended the upper end of the test's range from teenagers to "superior adults." He also gave his revision the name today's version retains—the [Stanford-Binet](#).

Stanford-Binet the widely used American revision (by Terman at Stanford University) of Binet's original intelligence test.

From such tests, German psychologist William Stern derived the famous term [intelligence quotient](#), or [IQ](#). The IQ was simply a person's mental age

divided by chronological age and multiplied by 100 to get rid of the decimal point. Thus, an average child, whose mental and chronological ages are the same, has an IQ of 100. But an 8-year-old who answers questions as would a typical 10-year-old has an IQ of 125:

intelligence quotient (IQ) defined originally as the ratio of mental age (*ma*) to chronological age (*ca*) multiplied by 100 (thus, $IQ = ma/ca \times 100$). On contemporary intelligence tests, the average performance for a given age is assigned a score of 100.

$IQ = \frac{\text{mental age of 10}}{\text{chronological age of 8}} \times 100 = 125$

$$IQ = \frac{\text{mental age of 10}}{\text{chronological age of 8}} \times 100 = 125$$

The original IQ formula worked fairly well for children but not for adults. (Should a 40-year-old who does as well on the test as an average 20-year-old be assigned an IQ of only 50?) Most current intelligence tests, including the Stanford-Binet, no longer compute an IQ in this manner (though the term *IQ* still lingers as a shorthand expression for “intelligence test score”). Instead, they assign a score that represents a test-taker’s performance *relative to the average performance* (which is arbitrarily set at 100) of others the same age. Intelligence test scores for most people—about 68 percent—fall between 85 and 115.

Terman (1916, [p. 4](#)) promoted the widespread use of intelligence testing to “take account of the inequalities of children in original endowment” by assessing their “vocational fitness.” In sympathy with Francis Galton’s *eugenics*—the much-criticized nineteenth-century movement that proposed measuring human traits and using the results to encourage only smart and fit people to reproduce—Terman envisioned that the use of intelligence tests would “ultimately result in curtailing the reproduction of feeble-mindedness and in the elimination of an enormous amount of crime, pauperism, and industrial inefficiency” ([p. 7](#)).

With Terman’s help, the U.S. government developed new tests to evaluate both newly arriving immigrants and World War I army recruits—the world’s first mass administration of an intelligence test. To some psychologists, the

results indicated the inferiority of people not sharing their Anglo-Saxon heritage. Such findings were part of the cultural climate that led to a 1924 immigration law that reduced Southern and Eastern European immigration quotas to less than a fifth of those for Northern and Western Europe.

Binet probably would have been horrified that his test had been adapted and used to draw such conclusions. Indeed, such sweeping judgments became an embarrassment to most of those who championed testing. Even Terman came to appreciate that test scores reflected not only people's innate mental abilities but also their education, native language, and familiarity with the culture assumed by the test. Abuses of the early intelligence tests serve to remind us that science can be value-laden. Behind a screen of scientific objectivity, ideology sometimes lurks.

Mrs. Randolph takes mother's pride too far.

Dave Coverly/Speed Bump

RETRIEVAL PRACTICE

RP-3 What is the IQ of a 4-year-old with a mental age of 5?

ANSWER: 125 ($5 \div 4 \times 100 = 125$)

David Wechsler: Testing Separate Strengths

Psychologist David Wechsler created what is now the most widely used individual intelligence test, the [Wechsler Adult Intelligence Scale \(WAIS\)](#), together with a version for school-age children (the *Wechsler Intelligence Scale for Children [WISC]*), and another for preschool children (Evers et al., 2012). The latest (2008) edition of the WAIS consists of 15 subtests, including these:

Wechsler Adult Intelligence Scale (WAIS) the WAIS and its companion versions for children are the most widely used intelligence tests; they contain verbal and performance (nonverbal) subtests.

- *Similarities*—reasoning the commonality of two objects or concepts (“In what way are wool and cotton alike?”)
- *Vocabulary*—naming pictured objects, or defining words (“What is a guitar?”)
- *Block Design*—visual abstract processing (“Using the four blocks, make

one just like this.”)

- *Letter-Number Sequencing*—on hearing a series of numbers and letters, repeating the numbers in ascending order, and then the letters in alphabetical order (“R-2-C-1-M-3”)

The WAIS yields not only an overall intelligence score, as does the Stanford-Binet, but also individual scores for verbal comprehension, perceptual organization, working memory, and processing speed. Striking differences among these individual scores can provide clues to cognitive strengths or weaknesses. For example, a low verbal comprehension score combined with high scores on other subtests could indicate a reading or language disability. Other comparisons can help a psychologist or psychiatrist establish a rehabilitation plan for a stroke patient. In such ways, these tests help realize Binet’s aim: to identify opportunities for improvement and strengths that teachers and others can build upon. Such uses are possible, of course, only when we can trust the test results.

Richard T. Nowitz/Getty Images

Matching patterns

Block design puzzles test visual abstract processing ability. Wechsler's individually administered intelligence test comes in forms suited for adults and children.

RETRIEVAL PRACTICE

RP-4 An employer with a pool of applicants for a single available position is interested in testing each applicant's potential. To determine that, she should use an _____ (achievement/aptitude) test. That same employer wishing to test the effectiveness of a new, on-the-job training program would be wise to use an _____ (achievement/aptitude) test.

ANSWER: aptitude; achievement

To learn more about the promise and perils of intelligence testing, watch the **Video: Locking Away the “Feeble-minded”—A Shameful History**. And to test your own performance on simulated WAIS subtasks, see **Concept Practice: Wechsler Intelligence Tasks**.

Principles of Test Construction

LOQ 10-6 What is a normal curve, and what does it mean to say that a test has been standardized and is reliable and valid?

To be widely accepted, a psychological test must meet three criteria: It must be *standardized*, *reliable*, and *valid*. The Stanford-Binet and Wechsler tests meet these requirements.

Standardization

The number of questions you answer correctly on an intelligence test would reveal almost nothing. To know how well you performed, you would need some basis for comparison. That’s why test-makers give new tests to a representative sample of people. The scores from this pretested group become the basis for future comparisons. If you then take the test following the same procedures, your score will be meaningful when compared with others. This process is called [standardization](#).

standardization defining uniform testing procedures and meaningful scores by comparison with the performance of a pretested group.

If we construct a graph of test-takers’ scores, the scores typically form a bell-shaped pattern called the *bell curve*, or [normal curve](#). No matter what attributes we measure—height, weight, or mental aptitude—the curve’s highest point is the average score. On an intelligence test, we give this average score a value of 100 ([FIGURE 10.4](#)). Moving out from the average, toward either extreme, we find fewer and fewer people. For both the Stanford-Binet and Wechsler tests, a person’s score indicates whether that

person's performance fell above or below the average. A performance higher than all but 2.5 percent of all scores earns an intelligence score of 130. A performance lower than 97.5 percent of all scores earns an intelligence score of 70.

normal curve the bell-shaped curve that describes the distribution of many physical and psychological attributes. Most scores fall near the average, and fewer and fewer scores lie near the extremes.

FIGURE 10.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.4 The normal curve

Scores on aptitude tests tend to form a normal, or bell-shaped, curve around an average score. For the Wechsler scale, for example, the average score is 100.

To keep the average score near 100, the Stanford-Binet and Wechsler scales are periodically restandardized. If you recently took the WAIS, Fourth Edition, your performance was compared with a standardization sample who took the test during 2007, not to David Wechsler's initial 1930s sample. If you compared the performance of the most recent standardization sample with that of the 1930s sample, do you suppose you would find rising or declining test performance? Amazingly—given that college entrance aptitude scores have sometimes dropped, such as during the 1960s and 1970s—intelligence test performance has improved. This worldwide phenomenon is called the *Flynn effect*, in honor of New Zealand researcher James Flynn (1987, 2012), who first calculated its magnitude. The average person's

intelligence test score in 1920 was—by today’s standard—only a 76! Such rising performance has been observed in 48 countries, from Canada to Cameroon (Wongupparaj et al., 2015). Although there have been some regional reversals, the historic increase is now widely accepted as an important phenomenon (Lynn, 2009; Teasdale & Owen, 2005, 2008).

The Flynn effect’s cause has been a psychological mystery. Did it result from greater test sophistication? *No*. Gains appeared before testing was widespread. Perhaps better nutrition? Thanks to improved nutrition, people have gotten taller as well as smarter. But in postwar Britain, notes Flynn (2009), the lower-class children gained the most from improved nutrition, yet the intelligence performance gains were greater among upper-class children. Might the explanation be greater educational opportunities, smaller families, and rising living standards (Pietschnig & Voracek, 2015; Rindermann et al., 2016)? Flynn (2012) attributes the performance increase to our need to develop new mental skills to cope with modern environments. Regardless of what combination of factors explains the rise in intelligence test scores, the phenomenon counters one concern of some hereditarians—that the higher twentieth-century birthrates among those with lower scores would shove human intelligence scores downward (Lynn & Harvey, 2008).

Reliability

Knowing where you stand in comparison to a standardization group still won’t say much about your intelligence unless the test has **reliability**. A reliable test gives consistent scores, no matter who takes the test or when they take it. To check a test’s reliability, researchers test people many times. They may split the test in half (*split-half*: agreement of odd-question scores and even-question scores), test with alternative forms of the test, or retest with the same test (*test-retest*). The higher the *correlation* between the two scores, the higher the test’s reliability. The tests we have considered—the Stanford-Binet, the WAIS, and the WISC—are very reliable after early childhood (about +0.9). When retested, people’s scores generally match their first score closely.

reliability the extent to which a test yields consistent results, as assessed by the consistency of scores on two halves of the test, on alternative forms of the

test, or on retesting.

Watch the **Video: Correlational Studies** for a helpful tutorial animation.

Validity

High reliability does not ensure a test's **validity**—the extent to which the test actually measures or predicts what it promises. Imagine using a miscalibrated tape measure to measure people's heights. Your results would be very reliable. No matter how many times you measured, people's heights would be the same. But your faulty height results would not be valid.

validity the extent to which a test measures or predicts what it is supposed to. (See also *content validity* and *predictive validity*.)

Tests that tap the pertinent behavior, or *criterion*, have **content validity**. The road test for a driver's license has content validity because it samples the tasks a driver routinely faces. Course exams have content validity if they assess one's mastery of course material. But we expect intelligence tests to have **predictive validity**: They should predict the criterion of future performance, and to some extent they do.

content validity the extent to which a test samples the behavior that is of interest.

predictive validity the success with which a test predicts the behavior it is designed to predict; it is assessed by computing the correlation between test scores and the criterion behavior. (Also called *criterion-related validity*.)

Are general aptitude tests as predictive as they are reliable? As critics are fond of noting, the answer is *No*. Aptitude test scores do predict school grades (Roth et al., 2015). But the critics are right that the predictive power of

aptitude tests peaks in the early school years and weakens later. Academic aptitude test scores are reasonably good predictors of achievement for children ages 6 to 12, where the correlation between intelligence score and school performance is about +0.6 (Jensen, 1980). Intelligence scores correlate even more closely with scores on *achievement* tests: +0.81 in one comparison of 70,000 English children's intelligence scores at age 11 with their academic achievement in national exams at age 16 (Deary et al., 2007, 2009b). The SAT, used in the United States as a college entrance exam, has been less successful in predicting first-year college grades. (The correlation, less than +0.5, has been, however, a bit higher when adjusting for high scorers electing tougher courses [Berry & Sackett, 2009; Willingham et al., 1990].) By the time we get to the Graduate Record Examination (GRE; an aptitude test similar to the SAT but for those applying to graduate school), the correlation with graduate school performance is an even more modest but still significant +0.4 (Kuncel & Hezlett, 2007).

Why does the predictive power of aptitude scores diminish as students move up the educational ladder? Consider a parallel situation: Among all American and Canadian football linemen, body weight correlates with success. A 300-pound player tends to overwhelm a 200-pound opponent. But within the narrow 280- to 320-pound range typically found at the professional level, the correlation between weight and success becomes negligible ([FIGURE 10.5](#)). The narrower the *range* of weights, the lower the predictive power of body weight becomes. If an elite university takes only those students who have very high aptitude scores, and then gives them a restricted range of high grades, those scores cannot possibly predict much. This will be true even if the test has excellent predictive validity with a more diverse sample of students. Likewise, modern grade inflation has produced less diverse high school grades. With their diminished range, high school grades now predict college grades no better than have SAT scores (Sackett et al., 2012). So, when we validate a measure using a wide range of scores but then use it with a restricted range of scores, it loses much of its predictive validity.

FIGURE 10.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.5 Diminishing predictive power

Let's imagine a correlation between football linemen's body weight and their success on the field. Note how insignificant the relationship becomes when we narrow the range of weight to 280 to 320 pounds. As the range of data under consideration narrows, its predictive power diminishes.

RETRIEVAL PRACTICE

RP-5 What are the three criteria that a psychological test must meet in order to be widely accepted? Explain.

ANSWER: A psychological test must be *standardized* (pretested on a representative sample of people), *reliable* (yielding consistent results), and *valid* (measuring and predicting what it is supposed to).

RP-6 Correlation coefficients were used in this section. Here's a quick review: Correlations do not indicate cause-effect, but they do tell us whether two things are associated in some way. A correlation of -1.00 represents perfect _____ (agreement/disagreement) between two sets of scores: As one score goes up, the other score goes _____ (up/down). A correlation of _____ represents no association. The highest correlation, $+1.00$, represents perfect _____ (agreement/disagreement): As the first score goes up, the other score goes _____ (up/down).

ANSWER: disagreement; down; zero; agreement; up

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The IQ of a 6-year-old with a measured mental age of 9 would be

- a. 67.
- b. 133.
- c. 86.
- d. 150.

The Wechsler Adult Intelligence Scale (WAIS) is best able to tell us

- a. what part of an individual's intelligence is determined by genetic inheritance.
- b. whether the test-taker will succeed in a job.
- c. how the test-taker compares with other adults in vocabulary and arithmetic reasoning.
- d. whether the test-taker has specific skills for music and the performing arts.

The Stanford-Binet, the Wechsler Adult Intelligence Scale, and the Wechsler Intelligence Scale for Children yield consistent results, for example on retesting. In other words, these tests have high

The Dynamics of Intelligence

Researchers are exploring some age-old questions about human intelligence. You know it: You are smarter than some people and not as smart as others. So what in that heart of smarts—the brain—creates this difference? Is it our brain's relative *size*? Our amounts of certain brain *tissue*? Our brain networks' *speed*? These are among the possibilities that researchers have identified.

Here we will focus on two other questions: How stable is intelligence over the life span? (Will the precocious 5-year-old mature into a talented college student and a brilliant senior citizen?) And what are the traits and talents of those at the low and high extremes of intelligence?

Stability or Change?

What happens to our intellectual muscles as we age? Do they gradually decline, as does our body strength? Or do they remain constant? To see how psychologists have studied intelligence, see Thinking Critically About: Cross-Sectional and Longitudinal Studies. The quest for answers to these questions illustrates psychology's self-correcting process.

LOQ 10-7 What are cross-sectional studies and longitudinal studies, and why is it important to know which method was used?

Thinking Critically About:
Cross-Sectional and Longitudinal Studies

Researchers using the **cross-sectional** method study different groups at one time. They have found that *mental ability declines with age*.¹

↓

Comparing 70-year-olds and 30-year-olds means comparing different people but also different eras. These researchers were comparing:

- generally less-educated people (born in the early 1900s) with better-educated people (born after 1950).
- people raised in large families with people raised in smaller families.
- people from less-affluent families with people from more-affluent families.

Researchers using the **longitudinal** method study and restudy the same group at different times in their life span. They have found that *intelligence remains stable, and on some tests it even increases*.²

↓

But these studies have their own issue. Participants who survive to the end may be the healthiest and brightest people. When researchers adjust for loss of participants, they find an intelligence decline, especially after age 85.³

1. Wechsler, 1972. 2. Salthouse, 2010, 2014; Schaie & Geiwitz, 1982. 3. Brayne et al., 1999.

cross-sectional study research that compares people of different ages at the same point in time.

longitudinal study research that follows and retests the same people over time.

RETRIEVAL PRACTICE

RP-7 Researcher A is well-funded to learn about how intelligence changes over the life span. Researcher B wants to study the intelligence of people who are now at various life stages. Which researcher should use the cross-sectional method, and which the longitudinal method?

ANSWER: Researcher A should develop a *longitudinal study* to examine how intelligence changes in the same people over the life span. Researcher B should develop a *cross-sectional study* to examine the intelligence of people now at various life stages.

Watch the **Video: Longitudinal and Cross-Sectional Studies** for a helpful tutorial animation.

Aging and Intelligence

LOQ 10-8 How does aging affect crystallized and fluid intelligence?

With the results of cross-sectional studies showing that older adults give fewer correct answers on intelligence tests than do younger adults, WAIS-creator David Wechsler (1972) concluded that “the decline of mental ability with age is part of the general [aging] process of the organism as a whole.” For a long time, this rather dismal view went unchallenged. Many corporations established mandatory retirement policies, assuming the

companies would benefit by replacing aging workers with younger, more capable employees. As “everyone knows,” you can’t teach an old dog new tricks.

After colleges in the 1920s began giving intelligence tests to entering students, several psychologists saw their chance to study intelligence longitudinally. They retested the same **cohort**—the same group of people—over a period of years (Schaie & Geiwitz, 1982). What they found was a surprise: Until late in life, intelligence remained stable. On some tests, scores even increased, due partly to experience with the tests (Salthouse, 2014) (**FIGURE 10.6**).

cohort a group of people sharing a common characteristic, such as from a given time period.

FIGURE 10.6 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Data from Schaie, 1994

FIGURE 10.6 Cross-sectional versus longitudinal testing of intelligence at various ages

In this test of one type of verbal intelligence (inductive reasoning), the cross-sectional method showed declining scores with age. The longitudinal method (in which the same people were retested over a period of years) showed a slight rise in scores well into adulthood.

The more optimistic results from longitudinal studies challenged the

presumption that intelligence sharply declines with age. Famed painter Anna Mary Robertson Moses (“Grandma Moses”) took up painting in her seventies, and at age 88 a popular magazine named her “Young Woman of the Year.” At age 89, architect Frank Lloyd Wright designed New York City’s Guggenheim Museum. As everyone knows, given good health you’re never too old to learn.

So the answers to our age-and-intelligence questions depend on what we assess and how we assess it. **Crystallized intelligence**—our accumulated knowledge as reflected in vocabulary and analogies tests—increases up to old age. **Fluid intelligence**—our ability to reason speedily and abstractly, as when solving novel logic problems—decreases beginning in the twenties and thirties, slowly up to age 75 or so, then more rapidly, especially after age 85 (Deary & Ritchie, 2016; Horn, 1982; Salthouse, 2009; 2013). With age, we lose and we win. We lose recall memory and processing speed, but we gain vocabulary and knowledge (Ackerman, 2014; **FIGURE 10.7**). Fluid intelligence may decline, but older adults’ social reasoning skills increase, as shown by an ability to take multiple perspectives, to appreciate knowledge limits, and to offer helpful wisdom in times of social conflict (Grossmann et al., 2010). Decisions also become less distorted by negative emotions such as anxiety, depression, and anger (Blanchard-Fields, 2007; Carstensen & Mikels, 2005).

crystallized intelligence our accumulated knowledge and verbal skills; tends to increase with age.

fluid intelligence our ability to reason speedily and abstractly; tends to decrease with age, especially during late adulthood.

FIGURE 10.7 With age, we lose and we win

Studies reveal that word power grows with age, while fluid intelligence declines.

“Knowledge is knowing a tomato is a fruit; wisdom is not putting it in a fruit salad.”

Anonymous

Age-related cognitive differences help explain why older adults are less likely to embrace new technologies (Charness & Boot, 2009; Pew, 2017). These cognitive differences also help explain why mathematicians and scientists produce much of their most creative work during their late twenties or early thirties, when fluid intelligence is at its peak (Jones et al., 2014). In contrast, authors, historians, and philosophers tend to produce their best work in their forties, fifties, and beyond—after accumulating more knowledge (Simonton, 1988, 1990). Poets, for example, who depend on fluid intelligence, reach their peak output earlier than prose authors, who need the deeper knowledge reservoir that accumulates with age. This finding holds in every major literary tradition, for both living and dead languages.

“We’re looking for someone with the wisdom of a 50-year-old, the experience of a 40-year-old, the drive of a 30-year-old, and the payscale of a 20-year-old.”

Stability Over the Life Span

LOQ 10-9 How stable are intelligence test scores over the life span?

What about the stability of early-life intelligence scores? For most children, casual observation and intelligence tests before age 3 only modestly predict their future aptitudes (Humphreys & Davey, 1988; Tasbihsazan et al., 2003). Even Albert Einstein was once thought “slow”—as he was in learning to talk (Quasha, 1980).

“In youth we learn, in age we understand.”

Marie Von Ebner-Eschenbach, *Aphorisms*, 1883

By age 4, however, children’s performance on intelligence tests begins to predict their adolescent and adult scores. The consistency of scores over time increases with the age of the child (Tucker-Drob & Briley, 2014). By age 11, the stability becomes impressive, as Ian Deary and his colleagues (2004, 2009b, 2013) discovered. Their amazing longitudinal studies have been enabled by their country, Scotland, doing something that no nation has done before or since. On June 1, 1932, essentially every child in the country born in 1921—87,498 children around age 11—took an intelligence test. The aim was to identify working-class children who would benefit from further education. Sixty-five years later to the day, Patricia Whalley, the wife of Deary’s co-worker, Lawrence Whalley, discovered the test results on dusty storeroom shelves at the Scottish Council for Research in Education, not far from Deary’s Edinburgh University office. “This will change our lives,” Deary replied when Whalley told him the news.

And so it has, with dozens of studies of the stability and the predictive capacity of these early test results. For example, when the intelligence test administered to 11-year-old Scots in 1932 was readministered to 542 survivors as turn-of-the-millennium 80-year-olds, the correlation between the two sets of scores—after nearly 70 years of varied life experiences—was striking ([FIGURE 10.8](#)). Ditto when 106 survivors were retested at age 90 (Deary et al., 2013). Another study that followed Scots born in 1936 from ages 11 to 70 confirmed the remarkable stability of intelligence, independent of life circumstance (Johnson et al., 2010).

FIGURE 10.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.8 Intelligence endures

When Ian Deary and his colleagues retested 80-year-old Scots, using an intelligence test they had taken as 11-year-olds, their scores across seven decades correlated $+0.66$, as shown here. (Data from Deary et al., 2004.) When 106 survivors were again retested at age 90, the correlation with their age 11 scores was $+0.54$ (Deary et al., 2013).

“Whether you live to collect your old-age pension depends in part on your IQ at age 11.”

Ian Deary, “Intelligence, Health, and Death,” 2005

Children and adults who are more intelligent also tend to live healthier and longer lives. Why might this be the case? Deary (2008) reports four possible explanations:

Intelligence facilitates more education, better jobs, and a healthier environment.

Intelligence encourages healthy living: less smoking, better diet, more exercise.

Prenatal events or early childhood illnesses might have influenced both intelligence and health.

A “well-wired body,” as evidenced by fast reaction speeds, perhaps fosters both intelligence and longevity.

Women scoring in the highest 25 percent on the Scottish national intelligence test at age 11 tended to live longer than those who scored in the lowest 25 percent. “On average,” reports Deary (2016), “a girl with a 30-point disadvantage in IQ on this 45-minute test at age 11 was half as likely to be alive” 65 years later.

Explore how researchers have studied these issues by engaging online with Immersive Learning: **How Would You Know If Intelligence Changes With Age?**

Extremes of Intelligence

LOQ 10-10 What are the traits of those at the low and high intelligence extremes?

One way to glimpse the validity and significance of any test is to compare people who score at the two extremes of the normal curve. The two groups should differ noticeably, and on intelligence tests, they do.

The Low Extreme

Intellectual disability (formerly called *mental retardation*) is a developmental condition that is apparent before age 18, sometimes with a known physical cause. (*Down syndrome*, for example, is a disorder of varying intellectual and physical severity caused by an extra copy of chromosome 21 in the person’s genetic makeup.) To be diagnosed with an intellectual disability, a person must meet two criteria. The first is low intellectual functioning as reflected in a low intelligence test score. Guidelines specify test score performance that is in the lowest 3 percent of the general population, or about 70 or below (Schalock et al., 2010). The second criterion is that the person must have difficulty adapting to the normal demands of independent living, as expressed in three areas, or skills: *conceptual* (language, reading, and concepts of money, time, and number); *social* (interpersonal skills, being socially responsible, following basic rules and laws, avoiding being victimized); and

practical (health and personal care, occupational skill, and travel). In mild forms, intellectual disability, like normal intelligence, results from a combination of genetic and environmental factors (Reichenberg et al., 2016).

intellectual disability a condition of limited mental ability, indicated by an intelligence test score of 70 or below and difficulty adapting to the demands of life. (Formerly referred to as *mental retardation*.)

When, thanks to the *Flynn effect*, intelligence tests are periodically restandardized, the intellectual-disability test score boundary can shift. Depending on when they were tested, two people with the same ability level could be classified differently (Kanaya et al., 2003; Reynolds et al., 2010). After one restandardization, individuals who scored near 70 on earlier tests suddenly lost about 6 test score points. As this has occurred, more people have become eligible for special education and financial assistance.

For some, intelligence test scores can mean life or death. In the United States (one of the only industrialized countries with the death penalty), the Flynn effect means fewer Americans are now eligible for execution: The U.S. Supreme Court ruled in 2002 that the execution of people with an intellectual disability—defined as a test score of below 70—is “cruel and unusual punishment.” For Teresa Lewis, that cutoff was high stakes. Lewis, a “dependent personality” with limited intellect, allegedly agreed to a plot in which two men killed her husband and stepson in exchange for a split of a life insurance payout (Eckholm, 2010). With a reported test score of 72, the State of Virginia executed Lewis in 2010. If only she had scored 69.

In 2014, the U.S. Supreme Court recognized the imprecision and arbitrariness of a fixed cutoff score of 70, and required states with death row inmates who have scored just above 70 to consider other evidence. Thus, Ted Herring, who had scored 72 and 74 on intelligence tests—but without knowing that summer follows spring or how to transfer between buses—was taken off Florida’s death row (Alvarez & Schwartz, 2014).

RETRIEVAL PRACTICE

RP-8 Why do psychologists NOT diagnose an intellectual

disability based solely on a person's intelligence test score?

ANSWER: An intelligence test score is only one measure of a person's ability to function. Other important factors to consider in an overall assessment include conceptual skills, social skills, and practical skills.

The High Extreme

Children whose intelligence test scores indicate extraordinary academic gifts mostly thrive. In one famous project begun in 1921, Lewis Terman studied more than 1500 California schoolchildren with IQ scores over 135. These high-scoring children (later called the “Termites”), like those in later studies, were healthy, well-adjusted, and unusually successful academically (Friedman & Martin, 2012; Koenen et al., 2009; Lubinski, 2009, 2016).

When restudied over the next seven decades, most people in Terman's group had attained high levels of education (Austin et al., 2002; Holahan & Sears, 1995). Many were doctors, lawyers, professors, scientists, and writers, though no Nobel Prize winners.

“My dear Adele, I am 4 years old and I can read any English book. I can say all the Latin substantives and adjectives and active verbs besides 52 lines of Latin poetry.”

Francis Galton, letter to his sister, 1827

Other studies have followed the lives of precocious youths who had aced the math SAT at age 13—by scoring in the top 1 percent of their age group. By their fifties, these 1650 math whizzes had secured 681 patents (Lubinski et al., 2014). Another group of 13-year-old verbal aptitude high scorers were, by age 38, twice as likely as the math aces to have become humanities professors or written a novel (Kell et al., 2013). About 1 percent of Americans earn doctorates. But for the 12- and 13-year-olds who scored in the top 1 in 10,000 among those of their age taking the SAT, about 4 in 10 had done so (Kell et al., 2013; Makel et al., 2016). One of psychology's whiz kids was Jean Piaget, who by age 15 was publishing scientific articles on

mollusks and who went on to become the twentieth century's most famous developmental psychologist (Hunt, 1993).

Terman did test two future Nobel laureates in physics, but they failed to score above his gifted sample cutoff (Hulbert, 2005).

Among the high-scoring whiz kids in national searches for precocious youth were Google co-founder Sergey Brin, Facebook's Mark Zuckerberg, and musician Stefani Germanotta (Lady Gaga) (Clynes, 2016). Another became a professional poker player with \$100,000+ annual earnings (Lubinski, 2016).

"Gifted child" programs tend to segregate high-scoring children in special classes, giving them academic enrichment not available to their peers. Critics note that tracking by aptitude sometimes creates a self-fulfilling prophecy: Implicitly labeling some children as "ungifted" and denying them opportunities for enriched education can widen the achievement gap between ability groups (Lipsey & Wilson, 1993; Stevenson & Lee, 1990). Because minority and low-income youth are more often placed in lower academic groups, tracking can also promote segregation and prejudice—hardly, note critics, a healthy preparation for working and living in a multicultural society.

Critics and proponents of gifted education do, however, agree on this: Children have differing gifts, whether at math, verbal reasoning, art, or social leadership. Some children exhibit exceptional potential or talent in a given domain. Educating children as if all were alike is as naive as assuming that giftedness is something, like blue eyes, that you either have or do not have. One need not hang labels on children to affirm their special talents and to challenge them all at the frontiers of their own ability and understanding. By providing *appropriate placement* suited to each child's talents (as when allowing a math whiz to study math at a higher level), we can promote both equity and excellence for all (Subotnik et al., 2011).

"Zach is in the gifted-and-talented-and-you're-not class."

Genetic and Environmental Influences on Intelligence

Intelligence runs in families. But why? Are our intellectual abilities mostly inherited? Or are they molded by our environment? Few issues arouse so much passion. If we mainly inherit our intelligence, then people's socioeconomic standing will correspond to their inborn differences. But if intelligence is mainly nurtured by our environments, then children from disadvantaged backgrounds can expect to lead disadvantaged lives—but with some hope that changing the environment could produce more intelligent and accomplished adults. Let's examine some of the evidence.

"I told my parents that if grades were so important they should have paid for a smarter egg donor."

Donald Reilly The New Yorker Collection/
The Cartoon Bank

Twin and Adoption Studies

LOQ 10-11 What evidence points to a genetic influence on

intelligence, and what is *heritability*?

Do people who share the same genes also share mental abilities? As you can see from [FIGURE 10.9](#), which summarizes many studies, the answer is clearly Yes. Consider:

FIGURE 10.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from McGue et al., 1993; Christopher Fitzgerald/The Image Works

FIGURE 10.9 Intelligence: Nature and nurture

The most genetically similar people have the most similar intelligence scores. Remember: 1.00 indicates a perfect correlation; zero indicates no correlation at all.

- The intelligence test scores of identical twins raised together are nearly as similar as those of the same person taking the same test twice (Haworth et al., 2009; Lykken, 2006; Plomin et al., 2016). (The scores of fraternal twins, who share only about half their genes, differ more.) Estimates of the [heritability](#) of intelligence—the extent to which intelligence test score variation within a group can be attributed to genetic variation—range from 50 to 80 percent (Madison et al., 2016; Plomin et al., 2016). Identical twins also exhibit substantial similarity (and heritability) in specific talents, such as music, math, and sports. Heredity accounts for more than half the variation in the national math and science exam scores of British 16-year-olds (Shakeshaft et al., 2013; Vinkhuyzen et al., 2009).
- Scans reveal that identical twins' brains have similar gray- and white-matter volume, and the areas associated with verbal and spatial intelligence are virtually the same (Deary et al., 2009a; Thompson et al., 2001). Their brains also show similar activity while doing mental tasks (Koten et al., 2009).
- Are there known genes for genius? When 200 researchers pooled their data on 126,559 people, all of the gene variations analyzed accounted for only about 2 percent of the differences in educational achievement (Rietveld et

al., 2013, 2014). This result was not a fluke; others have replicated this modest effect of genes on educational achievement (Belsky et al., 2016). And using a new genetic method, a follow-up British study recently found genes that predicted 9 percent of the variation in school achievement at age 16 (Selzam et al., 2016). This much seems clear: *Intelligence is polygenetic*, involving many genes. Wendy Johnson (2010) likens the polygenetic effect to height: 54 specific gene variations together account for 5 percent of our individual height differences, leaving the rest yet to be discovered. What matters for intelligence—as for height, personality, sexual orientation, schizophrenia or just about any human trait—is the combination of many genes (Plomin et al., 2016).

heritability the proportion of variation among individuals in a group that we can attribute to genes. The heritability of a trait may vary, depending on the range of populations and environments studied.

Other evidence points to environment effects:

- Where environments vary widely, as they do among children of less-educated parents, environmental differences are more predictive of intelligence scores (Tucker-Drob & Bates, 2016).
- Adoption enhances the intelligence scores of mistreated or neglected children (van IJzendoorn & Juffer, 2005, 2006). So does adoption from poverty into middle-class homes (Nisbett et al., 2012). In one large Swedish study, children adopted into wealthier families with more educated parents had IQ scores averaging 4.4 points higher than their not-adopted biological siblings (Kendler et al., 2015a).
- The intelligence scores of “virtual twins”—same-age, unrelated siblings adopted as infants and raised together—correlate +0.28 (Segal et al., 2012). This suggests a modest influence of their shared environment.

Seeking to disentangle genes and environment, researchers have also compared the intelligence test scores of adopted children with those of (a) their *biological parents* (the providers of their genes) and (b) their *adoptive parents* (the providers of their home environment). Over time, adopted

children accumulate experience in their differing adoptive families. So, would you expect the family-environment effect to grow with age and the genetic-legacy effect to shrink?

"Selective breeding has given me an aptitude for the law, but I still love fetching a dead duck out of freezing water."

Leo Cullum/The New Yorker Collection/
The Cartoon Bank

If you would, behavior geneticists have a stunning surprise for you. Mental similarities between adopted children and their adoptive families wane with age (McGue et al., 1993). Adopted children's intelligence scores resemble those of their biological parents much more than their adoptive parents (Loehlin, 2016). Genetic influences—not environmental ones—become more apparent as we accumulate life experience. Identical twins' similarities, for example, continue or increase into their eighties. Thus, report Ian Deary and his colleagues (2009a, 2012), the heritability of general intelligence increases from "about 30 percent" in early childhood to "well over 50 percent in adulthood." In one massive study of 11,000 twin pairs in four countries, the heritability of general intelligence (*g*) increased from 41 percent in middle childhood to 55 percent in adolescence to 66 percent in young adulthood (Haworth et al., 2010). Similarly, adopted children's verbal ability scores over time become more like those of their biological parents ([FIGURE 10.10](#)). Who would have guessed?

FIGURE 10.10 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Plomin & DeFries, 1998

FIGURE 10.10 In verbal ability, whom do adopted children resemble?

As the years went by in their adoptive families, children's verbal ability scores became more like their *biological* parents' scores.

RETRIEVAL PRACTICE

RP-9 A check on your understanding of heritability: If environments become more equal, the heritability of intelligence will

- a. increase.
- b. decrease.
- c. be unchanged.

ANSWER: a. (Heritability—variation explained by genetic influences—will increase as environmental variation decreases.)

For a helpful tutorial animation, watch the **Video: Twin Studies**. Then try to predict the correlation of intelligence scores in **Concept Practice: Studying Twins and Adopted Children**.

Environmental Influences

LOQ 10-12 What does evidence reveal about environmental

influences on intelligence?

Genes matter. Even if we were all raised in the same intellectually stimulating environment, we would have differing aptitudes. But life experiences also matter. Human environments are rarely as impoverished as the dark and barren cages inhabited by deprived rats that develop thinner-than-normal brain cortices (Rosenzweig, 1984). Yet severe deprivation also leaves footprints on the human brain.

Early Environmental Influences

Nowhere is the intertwining of biology and experience more apparent than in the most hopeless human environments, such as J. McVicker Hunt (1982) observed in a destitute Iranian orphanage. The typical child Hunt observed there could not sit up unassisted at age 2 or walk at age 4. The little care the infants received was not in response to their crying, cooing, or other behaviors, so the children developed little sense of personal control over their environment. They were instead becoming passive “glum lumps.” Extreme deprivation was bludgeoning native intelligence—a finding confirmed by studies of children raised in poorly run orphanages in Romania and elsewhere (Nelson et al., 2009, 2013; van IJzendoorn et al., 2008).

Josef Polleross/The Image Works

Devastating neglect

Some Romanian orphans, such as this child in the Leaganul Pentru Copii orphanage in 1990, had minimal interaction with caregivers, and suffered delayed development.

Aware of both the dramatic effects of early experiences and the impact of

early intervention, Hunt began a training program for the Iranian caregivers, teaching them to play language-fostering games with 11 infants. They imitated the babies' babbling, engaged them in vocal follow-the-leader, and, finally, they taught the infants sounds from the Persian language. The results were dramatic. By 22 months of age, the infants could name more than 50 objects and body parts, and so charmed visitors that most were adopted—an unprecedented success for the orphanage.

Hunt's findings are an extreme case of a more general finding: Poor environmental conditions can depress cognitive development. Schools with many poverty-level children often have less-qualified teachers, as one study of 1450 Virginia schools found (Tuerk, 2005). And these factors predicted lower achievement scores.

Poverty-related stresses also impede cognitive *performance* (Heberle & Carter, 2015). Like a computer that slows when running multiple operations, impoverished people's worries and distractions consume cognitive bandwidth and can diminish their thinking capacity. For example, on tests of cognitive functioning, sugar cane farmers in India scored better after being paid for their harvest—when their money worries dropped (Mani et al., 2013). Poverty can deplete cognitive capacity.

So, extreme conditions—sensory deprivation, social isolation, poverty—can slow normal brain development. Is the reverse also true? Will an “enriched” environment give children a superior intellect? Most experts are doubtful (Bruer, 1999; DeLoache et al., 2010; Reichert et al., 2010). There is no environmental recipe for fast-forwarding a normal infant into a genius. All babies should have normal exposure to sights, sounds, and speech. Although preschool experiences matter, Sandra Scarr's (1984) verdict still is widely shared: “Parents who are very concerned about providing special educational lessons for their babies are wasting their time.”

Schooling and Intelligence

EARLY INTERVENTION Later in childhood, schooling is one intervention that pays intelligence score dividends. Schooling and intelligence interact, and both enhance later income (Ceci & Williams, 1997, 2009). Hunt was a strong believer in the ability of education to boost children's chances for success by developing their cognitive and social skills. Indeed, his 1961

book, *Intelligence and Experience*, helped launch Project Head Start in 1965, a U.S. government-funded preschool program that has served more than 30 million children, most of whom come from families below the poverty level (Head Start, 2013). Does it succeed? Studies suggest that Head Start increases school readiness and gives a modest boost to later health and high school completion rate (Deming, 2009; Mervis, 2011; Pianta et al., 2009). Generally, however, aptitude benefits fade out over time (reminding us that life experiences *after* Head Start matter, too).

More encouraging results come from intensive post-babyhood preschool programs (Dodge et al., 2017; Tucker-Drob, 2012). Across a number of experiments, intelligence scores also rise with nutritional supplements to pregnant mothers and newborns (3.5 points), with quality preschool experiences (4 points), and with interactive reading programs (6 points) (Protzko et al., 2013).

Genes and experience together weave the fabric of intelligence. (*Epigenetics* is one field that studies this nature–nurture meeting place.) But what we accomplish with our intelligence depends also on our own beliefs and motivation. One analysis of 72,431 undergraduates found that study motivation and study skills rivaled aptitude and previous grades as predictors of academic achievement (Credé & Kuncel, 2008). Motivation can even affect intelligence test performance. Four dozen studies show that, when promised money for doing well, adolescents score higher on such tests (Duckworth et al., 2011).

Dave Nagel/Getty Images

The hungry mind

GROWTH MINDSET These observations would not surprise psychologist Carol Dweck (2006, 2015a,b, 2016). She reports that believing intelligence is changeable fosters a *growth mindset*, a focus on learning and growing. Dweck teaches young teens that the brain is like a muscle, growing stronger with use as neuron connections grow: “Learning how to do a new kind of problem grows your math brain!” Receiving praise for *effort* and for tackling challenges, rather than being smart or accomplished, helps teens understand the link between hard work and success (Gunderson et al., 2013). They also become more resilient when others frustrate them (Paunesku et al., 2015; Yeager et al., 2013, 2014, 2016a). Indeed, superior achievements in fields from sports to science to music arise from the combination of ability, opportunity, and disciplined effort (Ericsson et al., 2007).

More than 300 studies confirm that ability + opportunity + motivation = success. Extremely high intelligence-test-scoring 12-year-olds are much more likely than the average person to earn doctorates and hold patents—if their ability is “coupled with commitment” (Makel et al., 2016). High school students’ math proficiency and college students’ grades reflect their aptitude but also their self-discipline, their belief in the power of effort, and a curious,

“hungry mind” (Murayama et al., 2013; Richardson et al., 2012; von Stumm et al., 2011). In a study of 168,000 Chilean tenth graders, those from the lowest-income families who had a growth mindset had academic test scores comparable to high-income students who had a fixed mindset (Claro et al., 2016). And consider: South Asian-Americans won all nine U.S. national spelling bee contests between 2008 and 2016, an incredible achievement likely influenced by a cultural belief that strong effort will bring success (Rattan et al., 2012; Shankar, 2016).

“It is our choices . . . that show what we truly are, far more than our abilities.”

Professor Dumbledore to Harry Potter in J. K. Rowling’s *Harry Potter and the Chamber of Secrets*, 1999

These repeated findings—that a growth mindset and disciplined effort enhance achievement—have generated media attention and encouraged large-scale interventions with at-risk students. One downside, caution some researchers, is a possible overemphasis on positive thinking’s power to lift people out of disadvantage. Doing so comes at a social cost—blaming struggling individuals for their circumstances (Ikizer & Blanton, 2016). Sometimes people need more than the power of positive thinking to overcome their harsh conditions.

U.S. spelling champs

Nihar Janga, 11, and Jairam Hathwar, 13, celebrate their co-winning the 2016 Scripps National Spelling Bee. What were Nihar and Jairam’s winning words? “Gesellschaft” and “Feldenkrais.”

Group Differences in Intelligence Test Scores

If there were no group differences in aptitude scores, psychologists would have less debate over hereditary and environmental influences. But there are group differences. What are they? And what shall we make of them?

Gender Similarities and Differences

LOQ 10-13 How and why do the genders differ in mental ability scores?

In science as in everyday life it is differences, not similarities, that excite interest. In worldwide studies, men estimate their own intelligence higher than do females (Furnham, 2016). Yet compared with the anatomical and physiological differences between men and women, our intelligence differences are minor. In that 1932 testing of all Scottish 11-year-olds, for example, girls' average intelligence score was 100.6 and boys' was 100.5 (Deary et al., 2003). So far as *g* is concerned, boys and girls, and men and women, are the same species.

Yet, most people find differences more newsworthy. Girls outpace boys in spelling, verbal fluency, locating objects, detecting emotions, and sensitivity to touch, taste, and color (Halpern et al., 2007; Voyer & Voyer, 2014). Boys outperform girls in tests of spatial ability and complex math problems, though in math computation and overall math performance, boys and girls hardly differ (Else-Quest et al., 2010; Hyde & Mertz, 2009; Lindberg et al., 2010). Males' mental ability scores also vary more than females'. Thus, boys worldwide outnumber girls at both the low extreme and the high extreme (Brunner et al., 2013). Boys, for example, are more often found in special education classes, but also among those scoring very high on the SAT math test.

Give females long-term testosterone therapy (for female-to-male sex reassignment) and their brain language processing areas become, after losing some gray matter, more male-like (Hahn et al., 2016).

The most reliable male edge appears in spatial ability tests like the one

shown in [FIGURE 10.11](#) (Maeda & Yoon, 2013; Palejwala & Fine, 2015). The solution requires speedy mental rotation of three-dimensional objects. Today, such skills help when fitting suitcases into a car trunk, playing chess, or doing certain types of geometry problems. From an evolutionary perspective, those same skills would have helped our ancestral fathers track prey and make their way home (Geary, 1995, 1996; Halpern et al., 2007). The survival of our ancestral mothers may have benefited more from a keen memory for the location of edible plants—a legacy that lives today in women’s superior memory for objects and their location.

FIGURE 10.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 10.11 A mental rotation test

This illustrates the type of items found on a spatial abilities test. See [answer below.1](#)

Evolutionary psychologist Steven Pinker (2005) has argued that biology affects gender differences in life priorities (women’s somewhat greater interest in people versus men’s in money and things), in risk-taking (with men more reckless), and in math reasoning and spatial abilities. Such differences are, he noted, observed across cultures, stable over time, influenced by prenatal hormones, and observed in genetic boys raised as girls.

But social influences also construct gender. Stephen Ceci and Wendy Williams (2010, 2011) report that culturally influenced preferences help explain why American women, more than men, avoid math-intensive vocations. Social expectations and divergent opportunities also shape boys' and girls' interests and abilities (Crawford et al., 1995; Eccles et al., 1990). In Asia and Russia, teen girls have outperformed boys in an international science exam; in North America and Britain, boys have scored higher (Fairfield, 2012). More gender-equal cultures, such as Sweden and Iceland, exhibit little of the gender math gap found in gender-unequal cultures, such as Turkey and Korea (Guiso et al., 2008; Kane & Mertz, 2012). Since the 1970s, as gender equity has increased in the United States, the boy-to-girl ratio among 12- to 14-year-olds with very high SAT math scores (above 700) has declined from 13 to 1 to 3 to 1 (Nisbett et al., 2012). And in psychology, there's been a dramatic change in the ratio of women to men earning doctorates—from 17 percent women in 1958 to 70 percent in 2015 (Burelli, 2008; NSF, 2016a). Experience matters.

NASA/Getty Images

Minding the math gap

In 2014, Iranian math professor Maryam Mirzakhani (1977–2017) became the first woman to win math's most admired award, the Fields Medal. What was her advice to people who want to know more about math? Practice patience. "The beauty of mathematics," Mirzakhani said, "only shows itself to more patient followers" (*The Guardian*, 2014).

Larry Williams/Getty Images

Racial and Ethnic Similarities and Differences

LOQ 10-14 How and why do racial and ethnic groups differ in mental ability scores?

Fueling the group-differences debate are two other disturbing but agreed-upon facts:

- Racial and ethnic groups differ in their average intelligence test scores.
- High-scoring people (and groups) are more likely to attain high levels of

education and income.

There are many group differences in average intelligence test scores. New Zealanders of European descent outscore native Maori New Zealanders. Israeli Jews outscore Israeli Arabs. Most Japanese outscore most Burakumin, a stigmatized Japanese minority. And White Americans have outsourced Black Americans. This Black-White difference has diminished somewhat in recent years, especially among children (Dickens & Flynn, 2006; Nisbett et al., 2012). Such *group* differences provide little basis for judging individuals. Worldwide, women outlive men by four years, but knowing only that you are male or female won't tell us how long you will live.

We have seen that heredity contributes to *individual* differences in intelligence. But group differences in a heritable trait may be entirely environmental. Consider one of nature's experiments: Allow some children to grow up hearing their culture's dominant language, while others, born deaf, do not. Then give both groups an intelligence test rooted in the dominant language, and (no surprise) those with expertise in that language will score higher (Braden, 1994; Steele, 1990; Zeidner, 1990). Although individual performance differences may be substantially genetic, the group difference is not ([FIGURE 10.12](#)).

FIGURE 10.12 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Information from Lewontin, 1976

FIGURE 10.12 Group differences and environmental impact

Even if the variation between members within a group reflects genetic differences, the average difference between groups may be wholly due to environment. Imagine that seeds from the same mixture are sown in different soils. Although height differences *within* each window box of flowers will be genetic, the height difference *between* the two groups will be environmental. (Information from Lewontin, 1976.)

Might the racial gap be similarly environmental? Consider:

Genetics research reveals that under the skin, we humans are remarkably alike. The average genetic difference between two Icelandic villagers or between two Kenyans greatly exceeds the group difference between Icelanders and Kenyans (Cavalli-Sforza et al., 1994; Rosenberg et al., 2002). Moreover, looks can deceive. Light-skinned Europeans and dark-skinned Africans are genetically closer than are dark-skinned Africans and dark-skinned Aboriginal Australians.

Race is not a neatly defined biological category. Many social scientists see race primarily as a social construction without well-defined physical boundaries, as each race blends seamlessly into the race of its geographical neighbors (Helms et al., 2005; Smedley & Smedley, 2005). In one genetic analysis of more than 160,000 people living in the United States, most with less than 28 percent African ancestry said they were White; those with more than 28 percent mostly said they were African-American (Byrc et al., 2015). Moreover, with increasingly mixed ancestries, more and more people defy neat racial categorization and self-identify as multiracial (Pauker et al., 2009).

The intelligence test performance of today's better-fed, better-educated, and more test-prepared population exceeds that of the 1930s population—by a greater margin than the intelligence test score of the average White today exceeds that of the average Black (Flynn, 2012; Pietschnig & Voracek, 2015; Trahan et al., 2014). One research review noted that the average intelligence test performance of today's sub-Saharan Africans is the same as that of British adults in 1948 (Wicherts et al., 2010). No one credits genetics for such generation-to-generation differences.

When Blacks and Whites have or receive the same pertinent knowledge, they exhibit similar information-processing skill. “The data support the view that cultural differences in the provision of information may account for racial differences in [intelligence test performance],” reported researchers Joseph Fagan and Cynthia Holland (2007a).

Schools and culture matter. Countries whose economies create a large wealth gap between rich and poor tend also to have a large rich-versus-poor intelligence test score gap (Nisbett, 2009). In China and Turkey, people in poorer regions have the lowest intelligence test scores, and those in wealthier regions have the highest (Lynn et al., 2015, 2016). Moreover, educational policies such as kindergarten attendance, school discipline, and instructional time per year predict national differences in intelligence and knowledge tests

(Lynn & Vanhanen, 2012; Rindermann & Ceci, 2009). Math achievement, aptitude test differences, and especially grades may reflect conscientiousness more than competence (Poropat, 2014). Asian students, who have outperformed North American students on such tests, have also spent 30 percent more time in school and much more time in and out of school studying math (Geary et al., 1996; Larson & Verma, 1999; Stevenson, 1992). Women in college and university similarly outperform equally able men, thanks partly to their greater conscientiousness (Keiser et al., 2016).

“Do not obtain your slaves from Britain, because they are so stupid and so utterly incapable of being taught.”

Cicero, 106—43 B.C.E.

In different eras, different ethnic groups have experienced golden ages—periods of remarkable achievement. Twenty-five hundred years ago, it was the Greeks and the Egyptians, then the Romans. In the eighth and ninth centuries, genius seemed to reside in the Arab world. Five hundred years ago, the Aztec Indians and the peoples of Northern Europe were the superachievers. Today, many people notice Asian technological genius and Jewish cultural success. Cultures rise and fall over centuries; genes do not. That fact makes it difficult to attribute a natural superiority to any racial or ethnic group.

RETRIEVAL PRACTICE

RP-10 The heritability of intelligence scores will be greater in a society marked by equal opportunity than in a society of peasants and aristocrats. Why?

ANSWER: Perfectly equal opportunity would create 100 percent heritability, because genes alone would account for any human differences.

The Question of Bias

LOQ 10-15 Are intelligence tests inappropriately biased? How does stereotype threat affect test-takers' performance?

If one assumes that *race* is a meaningful concept, the debate over racial differences in intelligence divides into three camps (Hunt & Carlson, 2007):

- There are genetically disposed racial differences in intelligence.
- There are socially influenced racial differences in intelligence.
- There are racial differences in test scores, but the tests are inappropriate or biased.

We have considered group difference from the first and second perspectives. Let's turn now to the third: Are intelligence tests biased? The answer depends on which of two very different definitions of *bias* we use.

TWO MEANINGS OF BIAS The *scientific* meaning of *bias* hinges on a test's validity—on whether it predicts future behavior only for some groups of test-takers. For example, if the SAT accurately predicted the college achievement of women but not that of men, then the test would be biased. In

this statistical meaning of the term, the near-consensus among psychologists (as summarized by the U.S. National Research Council's Committee on Ability Testing and the American Psychological Association's Task Force on Intelligence) has been that the major U.S. aptitude tests are *not* biased (Berry & Zhao, 2015; Neisser et al., 1996; Wigdor & Garner, 1982). The tests' predictive validity is roughly the same for women and men, for various races, and for rich and poor. If an intelligence test score of 95 predicts slightly below-average grades, that rough prediction usually applies equally to all.

But we can also consider a test biased if it detects not only innate differences in intelligence but also performance differences caused by cultural experiences. This in fact happened to Eastern European immigrants in the early 1900s. Lacking the experience to answer questions about their new culture, many were classified as "feebleminded." In this popular sense, intelligence tests are biased. They measure your developed abilities, which reflect, in part, your education and experiences.

You may have read examples of intelligence test items that make assumptions (for example, that a cup goes with a saucer). Such items bias the test (against those who do not use saucers). Could such questions explain cultural differences in test performance? In such cases, tests can be a vehicle for discrimination, consigning potentially capable children (some of whom may have a different native language) to unchallenging classes and dead-end jobs. Thus, some intelligence researchers recommend creating culture-neutral questions—such as assessing people's ability to learn novel words, sayings, and analogies—to enable *culture-fair* aptitude tests (Fagan & Holland, 2007b, 2009).

Defenders of the existing aptitude tests have noted that racial group differences persist on nonverbal items, such as counting digits backward (Jensen, 1983, 1998). Moreover, they add, blaming the test for a group's lower scores is like blaming a messenger for bad news. Why blame the tests for exposing unequal experiences and opportunities? If, because of malnutrition, people were to suffer stunted growth, would you blame the measuring stick that reveals it? If unequal past experiences predict unequal future achievements, a valid aptitude test will detect such inequalities.

So, test-makers' expectations can introduce bias in an intelligence test. This is consistent with an observation we have seen throughout this text: Our expectations and attitudes can influence our perceptions and behaviors. This

is also true for the person taking the test.

RETRIEVAL PRACTICE

RP-11 What is the difference between a test that is biased culturally and a test that is biased in terms of its validity?

ANSWER: A test may be culturally biased if higher scores are achieved by those with certain cultural experiences. That same test may not be biased in terms of validity if it predicts what it is supposed to predict. For example, the SAT may be culturally biased in favor of those with experience in the U.S. school system, but it does still accurately predict U.S. college success.

Test-Takers' Expectations When Steven Spencer and his colleagues (1997) gave a difficult math test to equally capable men and women, women did not do as well—except when they had been led to expect that women usually do as well as men on the test. Otherwise, something affected their performance. There was a “threat in the air” (Spencer et al., 2016). And with Claude Steele and Joshua Aronson, Spencer (2002) again observed this self-fulfilling [stereotype threat](#) when Black students performed worse after being reminded of their race just before taking verbal aptitude tests. Follow-up experiments have confirmed that negatively stereotyped minorities and women may have unrealized academic and professional potential (Grand, 2016; Nguyen & Ryan, 2008; Walton & Spencer, 2009). If, when taking an intelligence test or performing a work-related task, you are worried that your group or “type” often doesn’t do well, your self-doubts and self-monitoring may hijack your working memory and impair your performance (Hutchison et al., 2013). Such thoughts, and worries about what others are thinking about you, can be distracting. For such reasons, stereotype threat may impair attention, performance, and learning (Inzlicht & Kang, 2010; Rydell et al., 2010). Remove the threat—by labeling the assessment as a “warm-up” exercise rather than a “test”—and stereotyped minorities often perform better (Taylor & Walton, 2011).

stereotype threat a self-confirming concern that one will be evaluated based on a negative stereotype.

“Math class is tough!”

“Teen talk” talking Barbie doll (introduced July 1992, recalled October 1992)

Stereotype threat helps explain why Blacks have scored higher when tested by Blacks than when tested by Whites (Danso & Esses, 2001; Inzlicht & Ben-Zeev, 2000). It implies a possible effect of non-Black teachers having lower expectations for Black students than do Black teachers (Gershenson et al., 2016). And it gives us insight into why women have scored higher on math tests with no male test-takers present, and why women’s online chess performance drops sharply when they *think* they are playing a male opponent (Maass et al., 2008).

Steele (1995, 2010) concludes that telling students they probably won’t succeed (as is sometimes implied by remedial “minority support” programs) functions as a stereotype that can erode performance. Over time, such students may detach their self-esteem from academics and look for recognition elsewhere. Indeed, as African-American male students progress from eighth to twelfth grade, a growing disconnect appears between their grades and their self-esteem, and they tend to underachieve (Osborne, 1997).

One experiment randomly assigned some African-American seventh graders to write for 15 minutes about their most important values (Cohen et al., 2006, 2009). That simple exercise in self-affirmation boosted their semester grades in two replications. Can a brief confidence-boosting exercise actually increase school achievement? “It was hard for us to believe,” reported Geoffrey Cohen (2013), “but we’ve replicated it since,” including among women in college physics. Other research teams also have reproduced the benefits of the self-affirmation exercise (Bowen et al., 2013; Cohen & Sherman, 2014; Harackiewicz et al., 2014, 2016). When challenged to believe in their potential, increase their sense of belonging, or focus on intelligence as malleable, disadvantaged university students have likewise

earned markedly higher grades and have had lower dropout rates (Tibbetts et al., 2016; Yeager et al., 2016b).

* * *

What, then, can we realistically conclude about aptitude tests and bias? The tests are not biased in the scientific sense of failing to make valid statistical predictions for different groups. But they are indeed biased in one sense—sensitivity to performance differences caused by cultural experience. Are the tests discriminatory? Again, the answer can be *Yes* or *No*. In one sense, *Yes*, their purpose is to discriminate—to distinguish among individuals. In another sense, *No*, their purpose is to reduce discrimination by decreasing reliance on subjective criteria for school and job placement—who you know, how you dress, or whether you are the “right kind of person.” Civil service aptitude tests, for example, were devised to discriminate more fairly and objectively by reducing the political, racial, ethnic, and gender discrimination that preceded their use. Banning aptitude tests would lead those who decide on jobs and admissions to rely more on other considerations, such as personal opinion.

Perhaps, then, our goals for tests of mental abilities should be threefold. First, we should realize the benefits that intelligence testing pioneer Alfred Binet foresaw—to enable schools to recognize who might profit most from early intervention. Second, we must remain alert to Binet’s fear that intelligence test scores may be misinterpreted as literal measures of a person’s worth and potential. Third, we must remember that the competence that general intelligence tests sample is important; it helps enable success in some life paths. But it reflects only one aspect of personal competence (Stanovich et al., 2013, 2014a,b). Our rationality, practical intelligence, and emotional intelligence matter, too, as do other forms of creativity, talent, and character.

“Almost all the joyful things of life are outside the measure of IQ tests.”

Madeleine L’Engle, *A Circle of Quiet*, 1972

The point to remember: There are many ways of being successful; our differences are variations of human adaptability. Life’s great achievements

result not only from “can do” abilities (and fair opportunity) but also from “will do” motivation. Competence + Diligence = Accomplishment.

“[Einstein] showed that genius equals brains plus tenacity squared.”

Walter Isaacson, “Einstein’s Final Quest,” 2009

RETRIEVAL PRACTICE

RP-12 What psychological principle helps explain why women tend to perform more poorly when they believe their online chess opponent is male?

ANSWER: stereotype threat

TERMS AND CONCEPTS TO REMEMBER

Test yourself on these terms by trying to compose the definition before checking your answers.

[heritability](#), p. 379

[stereotype threat](#), p. 386

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The strongest support for heredity's influence on intelligence is the finding that

- a. identical twins, but not other siblings, have nearly identical intelligence test scores.
- b. the correlation between intelligence test scores of fraternal twins is not higher than that for other siblings.
- c. mental similarities between adopted siblings increase with age.
- d. children in impoverished families have similar intelligence scores.

To say that the heritability of intelligence is about 50 percent means that 50 percent of

- a. an individual's intelligence is due to genetic factors.
- b. the similarities between two groups of people are attributable to genes.
- c. the variation in intelligence within a group of people is attributable to genetic factors.
- d. an individual's intelligence is due to each parent's genes.

The environmental influence that has the clearest, most profound effect on intellectual development is

- a. exposing normal infants to enrichment programs before age 1.
- b. growing up in an economically disadvantaged home or neighborhood.
- c. being raised in conditions of extreme deprivation.
- d. being an identical twin.

_____ can lead to poor performance on tests by undermining test-takers' belief that they can do well on the test.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Achievement Motivation

How well I [DM] remember asking my first discussion question in a new introductory psychology class. Several hands rose, along with one left foot. The foot belonged to Chris Klein, who was the unlikeliest person to have made it to that class. At birth, Chris suffered oxygen deprivation that required 40 minutes of CPR. “One doctor wanted to let him go,” recalled his mother.

The result was severe cerebral palsy. With damage to the brain area that controls muscle movement, Chris is unable to control his constantly moving hands. He cannot feed, dress, or care for himself. And he cannot speak. But Chris can control his keen mind and his left foot. With that blessed foot he operates the joystick on his motorized wheelchair. Using his left big toe, he can type sentences, which his communication system can store, send, or speak. And Chris has *motivation*—lots of motivation.

When Chris was a high school student in suburban Chicago, three teachers doubted he would be able to leave home for college. Yet he persisted, and, with much support, attended my college called Hope. Five years later, as his left foot drove him across the stage to receive his diploma, his admiring classmates honored his achievement with a spontaneous standing ovation.

Today, Chris is an inspirational speaker for schools, churches, and community events, giving “a voice to those that have none, and a helping hand to those with disabilities.” He is writing a book, *Lessons from the Big Toe*. And he has found love and married.

Few of us face Chris Klein’s challenges. But we all seek to direct our energy in ways that will produce satisfaction and success. We are pushed by biological motives, such as hunger and sex, and social ones, such as the need

to belong. Chris Klein's fierce will to live, learn, and love highlights the essence of our own *motivations*, which energize and direct our lives.

Let's begin by looking at how psychologists have approached the study of motivation.

Basic Motivational Concepts

LOQ **LEARNING OBJECTIVE QUESTION** **11-1** How do psychologists define *motivation*? From what perspectives do they view motivated behavior?

Our **motivations** arise from the interplay between nature (the bodily “push”) and nurture (the “pulls” from our personal experiences, thoughts, and culture). Our motives drive our behavior. That is usually, but not always, for the better. If our motivations get hijacked, our lives go awry. Those with *substance use disorder*, for example, may find their cravings for an addictive substance override their longings for sustenance, safety, and social support.

motivation a need or desire that energizes and directs behavior.

In their attempts to understand motivated behavior, psychologists have viewed it from four perspectives:

- *Instinct theory* (now replaced by the *evolutionary perspective*) focuses on genetically predisposed behaviors.
- *Drive-reduction theory* focuses on how we respond to our inner pushes.
- *Arousal theory* focuses on finding the right level of stimulation.
- Abraham Maslow’s *hierarchy of needs* focuses on the priority of some needs over others.

Instincts and Evolutionary Theory

To qualify as an [instinct](#), a complex behavior must have a fixed pattern throughout a species and be unlearned (Tinbergen, 1951). Such unlearned behaviors include *imprinting* in birds and the return of salmon to their birthplace. A few human behaviors, such as infants' innate reflexes to root for a nipple and suck, also exhibit unlearned fixed patterns. *Instinct theory*, popular in the early twentieth century, viewed our instincts as the source of our motivations. But many more behaviors are directed by both physiological needs and psychological wants.

instinct a complex behavior that is rigidly patterned throughout a species and is unlearned.

Annika Erickson/Getty Images; James Warwick/Science Source

Same motive, different wiring

The more complex the nervous system, the more adaptable the organism. Both humans and weaverbirds satisfy their need for shelter in ways that reflect their inherited capacities. Human behavior is flexible; we can learn whatever skills we need to build a house. The bird's behavior pattern is fixed; it can build only this kind of nest.

Although instincts cannot explain most human motives, the underlying assumption endures in *evolutionary psychology*: Genes do predispose some species-typical behavior. We saw this in [Chapter 7](#)'s discussion of the limits that biological predispositions place on conditioning. And we will see this in later discussions of how evolution might influence our phobias, our helping behaviors, and our romantic attractions.

Drives and Incentives

In addition to our predispositions, we have *drives*. [Physiological needs](#) (such as for food or water) create an aroused, motivated state—a drive (such as hunger or thirst)—that pushes us to reduce the need. [Drive-reduction theory](#) explains that, with few exceptions, when a physiological need increases, so does our psychological drive to reduce it.

physiological need a basic bodily requirement.

drive-reduction theory the idea that a physiological need creates an aroused state (a drive) that motivates an organism to satisfy the need.

Drive reduction is one way our bodies strive for **homeostasis** (literally “staying the same”)—the maintenance of a steady internal state. For example, our body regulates its temperature in a way similar to a room’s thermostat. Both systems operate through feedback loops: Sensors feed room temperature to a control device. If the room’s temperature cools, the control device switches on the furnace. Likewise, if our body’s temperature cools, our blood vessels constrict to conserve warmth, and we feel driven to put on more clothes or seek a warmer environment (**FIGURE 11.1**).

homeostasis a tendency to maintain a balanced or constant internal state; the regulation of any aspect of body chemistry, such as blood glucose, around a particular level.

FIGURE 11.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 11.1 Drive-reduction theory

Drive-reduction motivation arises from *homeostasis*—an organism’s natural tendency to maintain a steady internal state. Thus, if we are water deprived, our thirst drives us to drink and to restore the body’s normal state.

Not only are we *pushed* by our need to reduce drives, we also are *pulled* by **incentives**—positive or negative environmental stimuli that lure or repel us. Given such stimuli, our underlying drives, such as for food or sex, become active impulses. And the more those impulses are satisfied and reinforced, the stronger the drive may become: As Roy Baumeister (2015) noted, “Getting begets wanting.” Thus, our learning influences our motives. Depending on our learning, the aroma of good food, whether roasted peanuts or toasted ants, can motivate our behavior. So can the sight of those we find attractive or threatening.

incentive a positive or negative environmental stimulus that motivates behavior.

When there is both a need and an incentive, we feel strongly driven. The food-deprived person who smells pizza baking may feel a strong hunger drive, and the baking pizza may become a compelling incentive. For each motive, we can therefore ask, “How is it pushed by our inborn physiological needs and pulled by learned incentives in the environment?”

Arousal Theory

We are much more than homeostatic systems, however. Some motivated behaviors actually *increase* rather than decrease arousal. Well-fed animals will leave their shelter to explore and gain information, seemingly in the absence of any need-based drive. Curiosity drives monkeys to monkey around trying to figure out how to unlock a latch that opens nothing or how to open a window that allows them to see outside their room (Butler, 1954). It drives newly mobile infants to investigate every accessible corner of the house. It drove students, in one experiment, to click on pens to see whether they did or didn’t deliver an electric shock (Hsee & Ruan, 2016). It drives the scientists whose work this text discusses. And it drives explorers and adventurers such as mountaineer George Mallory. Asked why he wanted to climb Mount Everest, Mallory famously answered, “Because it’s there.” Sometimes uncertainty brings excitement, which amplifies motivation (Shen et al., 2015). Those who, like Mallory, enjoy high arousal are most likely to seek out intense music, novel foods, and risky behaviors and careers (Roberti et al., 2004; Zuckerman, 1979, 2009). Although they have been called “sensation-seekers,” risk takers may also be motivated by a drive to master their emotions and actions (Barlow et al., 2013).

Science Source; Glenn Swier

Driven by curiosity

Young monkeys and children are fascinated by the unfamiliar. Their

drive to explore maintains an optimum level of arousal and is one of several motives that do not fill any immediate physiological need.

So, human motivation aims not to eliminate arousal but to seek optimum levels of arousal. Having all our biological needs satisfied, we feel driven to experience stimulation. Lacking stimulation, we feel bored and look for a way to increase arousal. If left alone in a room, most people prefer to do something—even (when given no other option) to self-administer mild electric shocks (Wilson et al., 2014). Moderate anxiety can be motivating—leading to higher levels of math achievement, for example (Wang et al., 2015c). However, given too much stimulation or stress, we look for a way to decrease arousal. In one experiment, people felt less stress when they cut back checking e-mail to three times a day rather than being continually accessible (Kushlev & Dunn, 2015).

Two early twentieth-century psychologists studied the relationship of arousal to performance and identified the [Yerkes-Dodson law](#): *moderate arousal leads to optimal performance* (Yerkes & Dodson, 1908). When taking an exam, for example, it pays to be moderately aroused—alert but not trembling with nervousness. (If already anxious, it's better not to become further aroused with caffeine.) Between bored low arousal and anxious hyperarousal lies a flourishing life. Optimal arousal levels depend on the task, with more difficult tasks requiring lower arousal for best performance (Hembree, 1988).

Yerkes-Dodson law the principle that performance increases with arousal only up to a point, beyond which performance decreases.

RETRIEVAL PRACTICE

RP-1 Performance peaks at lower levels of arousal for difficult tasks, and at higher levels for easy or well-learned tasks. (1) How might this phenomenon affect marathon runners? (2) How might this phenomenon affect anxious test-takers facing a difficult exam?

ANSWER: (1) Well-practiced runners tend to excel when aroused by

competition. (2) High anxiety about a difficult exam may disrupt test-takers' performance.

A Hierarchy of Needs

Some needs take priority. At this moment, with your needs for air and water hopefully satisfied, other motives—such as your desire to learn and achieve (discussed later in this chapter)—are energizing and directing your behavior. Let your need for water go unsatisfied, however, and your thirst will preoccupy you. Deprived of air, you'll find that your thirst disappears.

“Hunger is the most urgent form of poverty.”

Alliance to End Hunger, 2002

Abraham Maslow (1970) described these priorities as a [hierarchy of needs](#) ([FIGURE 11.2](#)). At the base of this pyramid are our physiological needs, such as for food and water. Only if these needs are met are we prompted to meet our need for safety, and then to satisfy our needs to give and receive love and to enjoy self-esteem. Beyond this, said Maslow (1971), lies the need to actualize one's full potential.

hierarchy of needs Maslow's pyramid of human needs, beginning at the base with physiological needs that must first be satisfied before higher-level safety needs and then psychological needs become active.

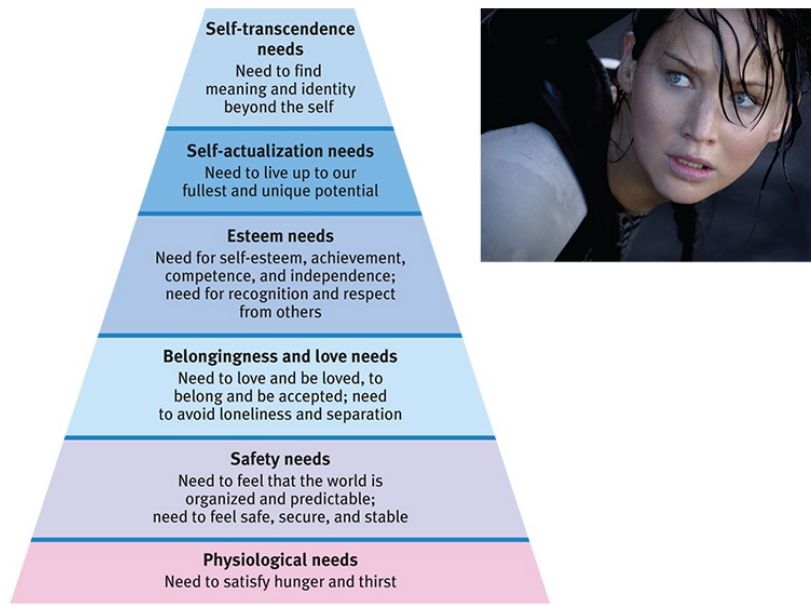

FIGURE 11.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 11.2 Maslow's hierarchy of needs

Reduced to near-starvation by their rulers, inhabitants of Suzanne Collins' fictional nation, Panem, hunger for food and survival. *Hunger Games* heroine Katniss Everdeen expresses higher-level needs for actualization and transcendence, and in the process inspires the nation.

Near the end of his life, Maslow proposed that some people also reach a level of *self-transcendence*. At the self-actualization level, people seek to realize their own potential. At the self-transcendence level, people strive for meaning, purpose, and communion in a way that is transpersonal—beyond the self (Koltko-Rivera, 2006). Maslow's contemporary, psychiatrist Viktor Frankl (1962), a Nazi concentration camp survivor, concurred that the search for meaning is an important human motive: "Life is never made unbearable by circumstances, but only by lack of meaning and purpose."

"Do you feel your life has an important purpose or meaning?" When Gallup asked that of people in 132 countries, 91 percent answered "Yes" (Oishi & Diener, 2014). Today's psychological scientists report that people sense meaning when they experience their life as having *purpose* (goals), *significance* (value), and *coherence* (making sense)—sentiments nourished by strong social connections, a religious faith, an orderly world, and social status (King et al., 2016; Martela & Steger, 2016). Moreover, meaning matters: People's sense of life's meaning predicts their psychological and physical well-being, and their capacity to cope with adversity (Heine et al.,

2006).

The order of Maslow's hierarchy is not universally fixed. People have starved themselves, for example, to make a political statement. Culture also influences our priorities: Self-esteem matters most in individualist nations, whose citizens tend to focus more on personal achievements than on family and community identity (Oishi et al., 1999). And, while agreeing with Maslow's basic levels of need, today's psychologists note that gaining and retaining mates, parenting offspring, and desiring social status are also universal human motives (Anderson et al., 2015; Kenrick et al., 2010).

Nevertheless, the simple idea that some motives are more compelling than others provides a framework for thinking about motivation. Worldwide life-satisfaction surveys support this basic idea (Oishi et al., 1999; Tay & Diener, 2011). In poorer nations that lack easy access to money and the food and shelter it buys, financial satisfaction more strongly predicts feelings of well-being. In wealthy nations, where most are able to meet their basic needs, social connections better predict well-being.

With these classic motivation theories in mind ([TABLE 11.1](#)), let's now consider four representative motives, beginning at the physiological level with hunger and working up through sexual motivation to the higher-level needs to belong and to achieve. At each level, we shall see how experience interacts with biology.

TABLE 11.1
Classic Motivation Theories

Theory	Its Big Idea
<i>Instinct theory/evolutionary psychology</i>	There is a genetic basis for unlearned, species-typical behavior (such as birds building nests or infants rooting for a nipple).
<i>Drive-reduction theory</i>	Physiological needs (such as hunger and thirst) create an aroused state that drives us to reduce the need (for example, by

	eating or drinking).
<i>Arousal theory</i>	Our need to maintain an optimal level of arousal motivates behaviors that meet no physiological need (such as our yearning for stimulation and our hunger for information).
<i>Maslow's hierarchy of needs</i>	We prioritize survival-based needs and then social needs more than the needs for esteem and meaning.

RETRIEVAL PRACTICE

RP-2 After hours of driving alone in an unfamiliar city, you finally see a diner. Although it looks deserted and a little creepy, you stop because you are *really* hungry and thirsty. How would Maslow's hierarchy of needs explain your behavior?

ANSWER: According to Maslow, our drive to meet the physiological needs of hunger and thirst takes priority over our safety needs, prompting us to take risks at times.

To test your understanding of the hierarchy of needs, engage online with **Concept Practice: Building Maslow's Hierarchy**.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Today's evolutionary psychology shares an idea that was an underlying assumption of instinct theory. This idea is that

- a. physiological needs arouse psychological states.
- b. genes predispose species-typical behavior.
- c. physiological needs increase arousal.
- d. external needs energize and direct behavior.

An example of a physiological need is _____. An example of a psychological drive is _____.

- a. hunger; a "push" to find food
- b. a "push" to find food; hunger
- c. curiosity; a "push" to reduce arousal

- d. a “push” to reduce arousal; curiosity

Danielle walks into a friend’s kitchen, smells cookies baking, and begins to feel very hungry. The smell of baking cookies is a(n) _____ (incentive/drive).

_____ theory attempts to explain behaviors that do NOT reduce physiological needs.

With a challenging task, such as taking a difficult exam, performance is likely to peak when arousal is

- a. very high.
- b. moderate.
- c. very low.
- d. absent.

According to Maslow’s hierarchy of needs, our most basic needs are physiological, including the need for food and water; just above these are _____ needs.

- a. safety
- b. self-esteem
- c. belongingness
- d. self-transcendence

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Hunger

As dieters know, physiological needs are powerful. This was vividly demonstrated when Ancel Keys and his research team (1950) studied semistarvation among wartime volunteers who participated as an alternative to military service. After feeding 200 men normally for three months, researchers halved the food intake for 36 of them. These semistarved men became listless and apathetic as their bodies conserved energy. Eventually, their body weights stabilized about 25 percent below their starting weights.

More dramatic were the psychological effects. Consistent with Maslow's idea of a needs hierarchy, the men became food obsessed. They talked food. They daydreamed food. They collected recipes, read cookbooks, and feasted their eyes on delectable forbidden foods. Preoccupied with their unfulfilled basic need, they lost interest in sex and social activities. As one participant reported, "If we see a show, the most interesting part of it is contained in scenes where people are eating. I couldn't laugh at the funniest picture in the world, and love scenes are completely dull." The men's preoccupations illustrate how powerful motives can hijack our consciousness.

"Nobody wants to kiss when they are hungry."

Journalist Dorothy Dix (1861–1951)

Pictures/REX/Shutterstock

Hunger hijacks the mind

World War II survivor Louis Zamperini (protagonist of the book and movie *Unbroken*, shown here) went down with his plane over the Pacific

Ocean. He and two other crew members drifted for 47 days, subsisting on an occasional bird or a fish. To help pass time, the hunger-driven men recited recipes or recalled their mothers' home cooking.

When you are hungry, thirsty, fatigued, or sexually aroused, little else may seem to matter. In University of Amsterdam studies, Loran Nordgren and his colleagues (2006, 2007) found that people in a motivational “hot” state (from fatigue, hunger, or sexual arousal) easily recalled such feelings in their own past and perceived them as driving forces in others' behavior. (You may recall from [Chapter 8](#) a parallel effect of our current good or bad mood on our memories of good and bad moods.) In another experiment, people were given money to bid for foods. When hungry, people *overbid* for snacks they were told they could eat later when they would be full. When full, people *underbid* for snacks they were told they could eat later when they would be hungry (Fisher & Rangel, 2014). It's hard to imagine what we're not feeling! Likewise, when sexually motivated, men more often perceive a smile as flirtation rather than simple friendliness (Howell et al., 2012). Grocery shop with an empty stomach and you are more likely to see those jelly-filled doughnuts as just what you've always loved and will be wanting tomorrow. *Motives matter mightily.*

“The full person does not understand the needs of the hungry.”

Irish proverb

The Physiology of Hunger

LOQ 11-2 What physiological factors produce hunger?

Keys' semistarved volunteers felt their hunger because of a homeostatic system that maintains one's normal body weight and an adequate nutrient supply. But what precisely triggers hunger? Is it the pangs of an empty stomach? So it seemed to A. L. Washburn. Working with Walter Cannon, Washburn agreed to swallow a balloon attached to a recording device (Cannon & Washburn, 1912) ([FIGURE 11.3](#)). When inflated to fill his stomach, the balloon transmitted his stomach contractions. Washburn supplied information about his *feelings* of hunger by pressing a key each time he felt a hunger pang. The discovery: Whenever Washburn felt hungry, he was indeed having stomach contractions.

FIGURE 11.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Information from Cannon, 1929.

FIGURE 11.3 Monitoring stomach contractions

“Nature often equips life’s essentials—sex, eating, nursing—with built-in gratification.”

Frans de Waal, “Morals Without God?,” 2010

Can hunger exist without stomach pangs? To answer that question, researchers removed some rats’ stomachs, creating a direct path to their small intestines (Tsang, 1938). Did the rats continue to eat? Indeed they did. Some hunger similarly persists in humans whose ulcerated or cancerous stomachs

have been removed.

If the pangs of an empty stomach are not the only source of hunger, what else matters?

Body Chemistry and the Brain

People and other animals automatically regulate their caloric intake to prevent energy deficits and maintain a stable body weight. This suggests that somehow, somewhere, the body is keeping tabs on its available resources. The blood sugar **glucose** is one such resource. Increases in the hormone *insulin* (secreted by the pancreas) diminish blood glucose, partly by converting it to stored fat. If your blood glucose level drops, you won't consciously feel the lower blood sugar. But your brain, which is automatically monitoring your blood chemistry and your body's internal state, will trigger hunger. Signals from your stomach, intestines, and liver (indicating whether glucose is being deposited or withdrawn) all signal your brain to motivate eating or not.

glucose the form of sugar that circulates in the blood and provides the major source of energy for body tissues. When its level is low, we feel hunger.

How does the brain integrate these messages and sound the alarm? The work is done by several neural areas, some housed deep in the brain within the hypothalamus, a neural traffic intersection (**FIGURE 11.4**). For example, one neural arc (called the *arcuate nucleus*) has a center that secretes appetite-stimulating hormones. When stimulated electrically, well-fed animals begin to eat. If the area is destroyed, even starving animals have no interest in food. Another neural center secretes appetite-suppressing hormones. When electrically stimulated, animals will stop eating. Destroy this area and animals can't stop eating and will become obese (Duggan & Booth, 1986; Hoebel & Teitelbaum, 1966).

FIGURE 11.4 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
ISM/Sovereign /Medical Images USA

FIGURE 11.4 The hypothalamus

The hypothalamus (colored orange) performs various body maintenance functions, including control of hunger. Blood vessels supply the hypothalamus, enabling it to respond to our current blood chemistry as well as to incoming neural information about the body's state.

Blood vessels connect the hypothalamus to the rest of the body, so it can respond to our current blood chemistry and other incoming information. One of its tasks is monitoring levels of appetite hormones, such as *ghrelin*, a hunger-arousing hormone secreted by an empty stomach. During bypass surgery for severe obesity, surgeons seal off or remove part of the stomach. The remaining stomach then produces much less ghrelin, and the person's appetite lessens (Ammori, 2013; Lemonick, 2002). Besides insulin and ghrelin, other appetite hormones include *leptin*, *orexin*, and *PYY*; [FIGURE 11.5](#) describes how they influence our feelings of hunger.

FIGURE 11.5 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 11.5 The appetite hormones

Increases appetite:

- *Ghrelin*: Hormone secreted by empty stomach; sends “I’m hungry” signals to the brain.
- *Orexin*: Hunger-triggering hormone secreted by hypothalamus.

Decreases appetite:

- *Insulin*: Hormone secreted by pancreas; controls blood glucose.
- *Leptin*: Protein hormone secreted by fat cells; when abundant, causes brain to increase metabolism and decrease hunger.
- *PYY*: Digestive tract hormone; sends “I’m *not* hungry” signals to the brain.

Experimental manipulation of appetite hormones has raised hopes for an

appetite-reducing medication. Such a nose spray or skin patch might counteract the body's hunger-producing chemicals or mimic (or even increase) the levels of hunger-dampening chemicals.

Voisin/Phanie/Science Source

Evidence for the brain's control of eating

The fat mouse on the left has nonfunctioning receptors in the appetite-suppressing part of the hypothalamus.

You can also blame your brain for weight regain (Cornier, 2011). The complex interaction of appetite hormones and brain activity helps explain the body's predisposition to maintain a particular weight. When semistarved rats fall below their normal weight, their "weight thermostat" signals the body to restore the lost weight. It's as though fat cells cry out "Feed me!" and grab glucose from the bloodstream (Ludwig & Friedman, 2014). Hunger increases and energy expenditure decreases. This stable weight toward which semistarved rats return is their [set point](#) (Keesey & Corbett, 1984). In rats and humans, heredity influences body type and approximate set point.

set point the point at which your "weight thermostat" may be set. When your

body falls below this weight, increased hunger and a lowered metabolic rate may combine to restore lost weight.

For an interactive and visual tutorial on the brain and eating, visit **PsychSim 6: Hunger and the Fat Rat**.

Our bodies regulate weight through the control of food intake, energy output, and **basal metabolic rate**—the resting rate of energy expenditure for maintaining basic body functions. By the end of their 6 months of semistarvation, the men who participated in Keys’ experiment had stabilized at three-quarters of their normal weight, although they were taking in *half* of their previous calories. How did they achieve this dieter’s nightmare? They reduced their energy expenditure, partly through inactivity but partly because of a 29 percent drop in their basal metabolic rate.

basal metabolic rate the body’s resting rate of energy output.

Some researchers, however, doubt that our bodies have a preset tendency to maintain optimum weight (Assanand et al., 1998). They point out that slow, sustained changes in body weight can alter one’s set point, and that psychological factors also sometimes drive our feelings of hunger. Given unlimited access to a wide variety of tasty foods, people and other animals tend to overeat and gain weight (Raynor & Epstein, 2001). For these reasons, some researchers prefer the term *settling point* to indicate the level at which a person’s weight settles in response to caloric intake and expenditure (which are influenced by environment as well as biology).

RETRIEVAL PRACTICE

RP-3 Hunger occurs in response to _____ (low/high) blood glucose and _____ (low/high) levels of ghrelin.

ANSWER: low; high

The Psychology of Hunger

LOQ 11-3 What cultural and situational factors influence hunger?

Our internal hunger is pushed by our physiology—our body chemistry and hypothalamic activity. Yet there is more to hunger than meets the stomach. This was strikingly apparent when Paul Rozin and his colleagues (1998) tested two patients with amnesia who had no memory for events occurring more than a minute ago. If, 20 minutes after eating a normal lunch, the patients were offered another, both readily consumed it . . . and usually a third meal offered 20 minutes after the second was finished. This suggests that part of knowing when to eat is our memory of our last meal. As time passes since we last ate, we anticipate eating again and start feeling hungry.

Taste Preferences: Biology and Culture

Body cues and environmental factors together influence not only the *when* of hunger, but also the *what*—our taste preferences. When feeling tense or depressed, do you tend to take solace in high-calorie foods, as ardent football fans have done after a big loss (Cornil & Chandon, 2013)? Carbohydrates boost the neurotransmitter serotonin, which has calming effects. When stressed, both rats and many humans find it extra rewarding to scarf Oreos (Artiga et al., 2007; Sproesser et al., 2014).

"Never get a tattoo when you're drunk and hungry."

The New Yorker Collection, 2002, Alex Gregory
from cartoonbank.com. All Rights Reserved.

Our preferences for sweet and salty tastes are genetic and universal. Other

taste preferences are conditioned, as when people given highly salted foods develop a liking for excess salt (Beauchamp, 1987), or when people who have been sickened by a food develop an aversion to it. (The frequency of children's illnesses provides many chances for them to learn food aversions.)

Culture affects taste, too. Many Japanese people enjoy *nattó*, a fermented soybean dish, which smell expert Rachel Herz (2012) reports “smells like the marriage of ammonia and a tire fire.” Asians, she adds, are often repulsed by what many Westerners love—“the rotted bodily fluid of an ungulate” (a.k.a. cheese, some varieties of which have the same bacteria and odor as stinky feet).

Rats tend to avoid unfamiliar foods (Sclafani, 1995). So do we, especially animal-based foods. Such *neophobia* (dislike of unfamiliar things) surely was adaptive for our ancestors, protecting them from potentially toxic substances. Disgust works. Nevertheless, in experiments, people who repeatedly sample an initially novel fruit drink or unfamiliar food typically experience increasing appreciation for the new taste. Moreover, exposure to one set of novel foods increases our willingness to try another (Pliner, 1982; Pliner et al., 1993).

Other taste preferences also are adaptive. For example, the spices most commonly used in hot-climate recipes—where food, especially meat, is at risk of spoiling more quickly—inhibit bacteria growth ([FIGURE 11.6](#)). Pregnancy-related nausea and food aversions peak about the tenth week, when the developing embryo is most vulnerable to toxins. So there is biological wisdom to our taste preferences.

FIGURE 11.6 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 11.6 Hot cultures like hot spices

Countries with hot climates, in which food historically spoiled more quickly, feature recipes with more bacteria-inhibiting spices (Sherman & Flaxman, 2001). India averages nearly 10 spices per meat recipe; Finland, 2 spices.

RICHARD OLSENIUS/National Geographic Creative; Mark Bowler/Alamy

An acquired taste

People everywhere learn to enjoy the fatty, bitter, or spicy foods common in their culture. For these Alaska Natives (left), but not for most other North Americans, whale blubber is a tasty treat. For Peruvians (right), roasted guinea pig is similarly delicious.

Situational Influences on Eating

To a surprising extent, situations also control our eating—a phenomenon psychologists have called the *ecology of eating*. Here are five situational influences you may have noticed but underestimated:

- *Arousing appetite* In one experiment, watching an intense action movie (rather than a nonarousing interview) doubled snacking (Tal et al., 2014).
- *Friends and food* Do you eat more when eating with others? Most of us do (Herman et al., 2003; Hetherington et al., 2006). After a party, you may realize you've overeaten. This happens because the presence of others tends to amplify our natural behavior tendencies. (More about this *social facilitation* in [Chapter 13](#).)
- *Serving size is significant* Researchers studied the effects of portion size by offering people varieties of free snacks (Geier et al., 2006). For example, in

an apartment building's lobby, they laid out either full or half pretzels, big or little Tootsie Rolls, or a small or large serving scoop by a bowl of M&M'S. Their consistent result: Offered a supersized portion, people put away more calories. Offered pasta, people eat more when given a bigger plate (Van Ittersum & Wansink, 2012). Larger portions induce bigger bites, which may increase intake by decreasing oral exposure time (Herman et al., 2015). Children also eat more when using adult-sized (rather than child-sized) dishware (DiSantis et al., 2013). Even nutrition experts helped themselves to 31 percent more ice cream when given a big bowl rather than a small one (Wansink, 2014; Wansink et al., 2006). Portion size matters.

- *Selections stimulate* Food variety also stimulates eating. Offered a dessert buffet, people eat more than they do when choosing a portion from one favorite dessert. For our early ancestors, variety was healthy. When foods were abundant and varied, eating more provided a wide range of vitamins and minerals and produced protective fat for winter cold or famine. When a bounty of varied foods was unavailable, eating less extended the food supply until winter or famine ended (Polivy et al., 2008; Remick et al., 2009).
- *Nudging nutrition* One research team quadrupled carrots taken by offering schoolchildren carrots before they picked up other foods in a lunch line (Redden et al., 2015). A new school lunch tray puts fruits and veggies up front, and spreads the main dish out in a shallow compartment to make it look bigger (Wansink, 2014). Such “nudges” support Barack Obama’s 2015 executive order to use “behavioral science insights to better serve the American people.”

* * *

Consider how researchers test some of these ideas by engaging online with **Immersive Learning: How Would You Know If Using Larger Dinner Plates Can Make Us Gain Weight?**

RETRIEVAL PRACTICE

RP-4 After an 8-hour hike without food, your long-awaited favorite

dish is placed in front of you, and your mouth waters in anticipation. Why?

ANSWER: You have learned to respond to the sight and aroma that signal the food about to enter your mouth. Both *physiological* cues (low blood sugar) and *psychological* cues (anticipation of the tasty meal) heighten your experienced hunger.

To consider how hunger and other factors affect our weight, see Thinking Critically About: The Challenges of Obesity and Weight Control. And for tips on shedding unwanted weight, see [TABLE 11.2](#).

TABLE 11.2

Waist Management

People struggling with obesity should seek medical evaluation and guidance. For others who wish to lose weight, researchers have offered these tips:
<ul style="list-style-type: none">• <i>Begin only if you feel motivated and self-disciplined.</i> Permanent weight loss usually requires a lifelong change in eating habits combined with increased exercise.
<ul style="list-style-type: none">• <i>Exercise and get enough sleep.</i> Especially when supported by 7 to 8 hours of sleep a night, exercise empties fat cells, builds muscle, speeds up metabolism, helps lower your settling point, and reduces stress and stress-induced craving for carbohydrate-rich comfort foods (Bennett, 1995; Ruotsalainen et al., 2015; Thompson et al., 1982).
<ul style="list-style-type: none">• <i>Minimize exposure to tempting food cues.</i> Food shop on a full stomach. Keep tempting foods out of the house, and tuck away special-occasion foods.
<ul style="list-style-type: none">• <i>Limit variety and eat healthy foods.</i> Given more variety, people consume more. So eat simple meals with vegetables, fruits, and

whole grains. Healthy fats, such as those found in olive oil and fish, help regulate appetite (Taubes, 2001, 2002). Water- and vitamin-rich veggies can fill the stomach with few calories. Better crispy greens than Krispy Kremes.

- **Reduce portion sizes.** Serve food with smaller bowls, plates, and utensils.

- **Don't starve all day and eat one big meal at night.** This common eating pattern slows metabolism. Moreover, those who eat a balanced breakfast are, by late morning, more alert and less fatigued (Spring et al., 1992).

- **Beware of the binge.** Drinking alcohol or feeling anxious or depressed can unleash the urge to eat (Herman & Polivy, 1980). And men especially should note that eating slowly can lead to eating less (Martin et al., 2007).

- Before eating with others, decide how much you want to eat. Eating with friends can distract us from monitoring our own eating (Ward & Mann, 2000).

- **Remember, most people occasionally lapse.** A lapse need not become a collapse.

- **Chart your progress online.** Those who record and publicly disclose their progress toward a goal more often achieve it (Harkin et al. 2016).

- **Connect to a support group.** Join with others, either face-to-face or online, to share goals and progress updates (Freedman, 2011).

Thinking Critically About: The Challenges of Obesity and Weight Control

LOQ 11-4 How does obesity affect physical and psychological health, and what factors are involved in weight management?

A Growing Problem

Obesity is associated with:

- **physical health risks**, including diabetes, high blood pressure, heart disease, gallstones, arthritis, and certain types of cancer.¹
- **increased depression**, especially among women.²
- **bullying**, outranking race and sexual orientation as the biggest reason for youth bullying in Western cultures.³

Percentage Overweight in 188 Countries Studied⁴

Body Mass Index (BMI)

How Did We Get Here?

Does obesity reflect a lack of willpower, as most people presume?⁷
No. Many factors contribute to obesity.

PHYSIOLOGY FACTORS

Storing fat was adaptive.

- This ideal form of stored energy carried our ancestors through periods of famine. People in impoverished places still find heavier bodies attractive, as plumpness signals affluence and status.⁸
- In food-rich countries, the drive for fat has become dysfunctional.⁹

Set point and metabolism matter.

- Fat (lower metabolic rate than muscle) requires less food intake to maintain than it did to gain.
- If weight drops below *set point/settling point*, the brain triggers **hunger** and **metabolism**.
- Body perceives **STARVATION**; adapts by burning fewer calories. Most dieters in the long run regain what they lose on weight-loss programs.¹⁰
- 30 weeks of competition on "The Biggest Loser" → 6 years later → Only 1 of 14 contestants kept the weight off. On average they regained 70% of what they lost and were still struggling with lessened caloric burn from their slowed metabolism.¹¹

Genes influence us.

- Lean people seem naturally disposed to move about, burning more calories than energy-conserving overweight people, who tend to sit still longer.¹²
- Adoptive siblings' body weights are uncorrelated with one another or with their adoptive parents, instead resembling biological parents' weight.¹³
- Identical twins have closely similar weights, even if raised apart.¹⁴ Much lower fraternal twin weight correlation suggests genes explain 2/3 of our varying body mass.¹⁵
- ~ 100 genes have been identified as each affecting weight in some small way.¹⁶

ENVIRONMENTAL FACTORS

- **Sleep loss** makes us more vulnerable to obesity.¹⁷

- **Social influences:** Our own odds of becoming obese triple if a close friend becomes obese.¹⁸
- **Food and activity levels:** Worldwide, we eat more and move less, with 31% of adults (including 43% of Americans and 25% of Europeans) now sedentary—averaging <20 minutes per day of moderate activity such as walking.¹⁹

NOTE: With weight, as with intelligence (see Chapter 10) and other characteristics, there can be high levels of *heritability* (genetic influence on individual differences) without heredity explaining *group* differences. Genes mostly determine why one person today is heavier than another. Environment mostly determines why people today are heavier than their counterparts 50 years ago.

RETRIEVAL PRACTICE

RP-5 Why can two people of the same height, age, and activity level maintain the same weight, even if one of them eats much less than the other does?

ANSWER: Genetically influenced set/settling points, metabolism, and other factors influence the way our bodies burn calories. Sleep deprivation, which makes us more vulnerable to weight gain, may also factor in.

For a 7-minute review of hunger, see the **Video: Hunger and Eating**.

REVIEW **Hunger**

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these

questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Journalist Dorothy Dix once remarked, "Nobody wants to kiss when they are hungry." How does Maslow's hierarchy of needs support her statement?

According to the concept of _____, our body maintains itself at a particular weight level.

Which of the following is a genetically predisposed response to food?

- a. An aversion to eating cats and dogs
- b. An interest in novel foods
- c. A preference for sweet and salty foods
- d. An aversion to carbohydrates

Blood sugar provides the body with energy. When it is

_____ (low/high), we feel hungry.

The rate at which your body expends energy while at rest is referred to as the _____ rate.

Obese people find it very difficult to lose weight permanently. This is due to several factors, including the fact that

- a. dieting triggers neophobia.
- b. the set point of obese people is lower than average.
- c. with dieting, metabolism increases.
- d. there is a genetic influence on body weight.

Sanjay recently adopted the typical college diet, increasing his intake of processed foods and sugar. He knows he may gain weight, but he figures it's no big deal because he can simply lose it in the future.

How would you evaluate Sanjay's plan?

Answers are a click away in the e-book, and available in [Appendix D](#), at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Sexual Motivation

Sex is a part of life. For all but the tiny fraction of us considered [asexual](#), dating and mating become a high priority from puberty on. Physiological and psychological influences affect our sexual feelings and behaviors.

asexual having no sexual attraction to others.

The Physiology of Sex

Sex is not like hunger, because it is not an actual *need*. (Without it, we may feel like dying, but we will not.) Yet sex motivates. Had this not been so for all your ancestors, you would not be alive and reading these words. Sexual motivation is nature's clever way of making people procreate, thus enabling our species' survival. Life is sexually transmitted.

“It is a near-universal experience, the invisible clause on one's birth certificate stipulating that one will, upon reaching maturity, feel the urge to engage in activities often associated with the issuance of more birth certificates.”

Science writer Natalie Angier, 2007

Hormones and Sexual Behavior

LOQ 11-5 How do hormones influence human sexual motivation?

Among the forces driving sexual behavior are the *sex hormones*. The main male sex hormone is [testosterone](#). The main female sex hormones are the [estrogens](#), such as *estradiol*. Sex hormones influence us at many points in the life span:

testosterone the most important male sex hormone. Both males and females have it, but the additional testosterone in males stimulates the growth of the male sex organs during the fetal period and the development of the male sex characteristics during puberty.

estrogens sex hormones, such as estradiol, that contribute to female sex characteristics and are secreted in greater amounts by females than by males. Estrogen levels peak during ovulation. In nonhuman mammals, this promotes sexual receptivity.

- During the prenatal period, they direct our development as males or females.
- During puberty, a sex hormone surge ushers us into adolescence.
- After puberty and well into the late adult years, sex hormones facilitate sexual behavior.

In most mammals, nature neatly synchronizes sex with fertility. Females become sexually receptive when their estrogens peak at ovulation, and researchers can cause female animals to become receptive by injecting them with estrogens. Male hormone levels are more constant, and hormone injection does not so easily affect the sexual behavior of male animals (Piekarski et al., 2009). Nevertheless, male hamsters that have had their testosterone-making testes surgically removed will gradually lose much of their interest in receptive females. They gradually regain it if injected with testosterone.

Hormones do influence human sexual behavior, but more loosely. Researchers are exploring and debating whether women's mate preferences change across the menstrual cycle (Gildersleeve et al., 2014; Wood et al., 2014a). At ovulation, women's estrogens surge—as does their testosterone, though not as much. Some evidence suggests that, among women with mates, sexual desire rises slightly at ovulation—a change that men can sometimes detect in women's behaviors and voices (Haselton & Gildersleeve, 2011, 2016).

Women have much less testosterone than men do. And more than other mammalian females, women are responsive to their testosterone level (Davison & Davis, 2011; van Anders, 2012). If a woman's natural

testosterone level drops, as happens with removal of the ovaries or adrenal glands, her sexual interest may wane. And as experiments with surgically or naturally menopausal women have demonstrated, testosterone-replacement therapy can often restore diminished sexual activity, arousal, and desire (Braunstein et al., 2005; Buster et al., 2005; Petersen & Hyde, 2011).

In human males with abnormally low testosterone levels, testosterone-replacement therapy often increases sexual desire and also energy and vitality (Khera et al., 2011). But normal fluctuations in testosterone levels, from man to man and hour to hour, have little effect on sexual drive (Byrne, 1982). Indeed, male hormones sometimes vary in *response* to sexual stimulation (Escasa et al., 2011). In one study, Australian skateboarders' testosterone surged in the presence of an attractive female, contributing to riskier moves and more crash landings (Ronay & von Hippel, 2010). Thus, sexual arousal can be a *cause* as well as a consequence of increased testosterone levels.

Large hormonal surges or declines affect sexual desire in shifts at two predictable points in the life span, and sometimes at an unpredictable third point:

- . *The pubertal surge in sex hormones triggers the development of sex characteristics and sexual interest.* If the hormonal surge is precluded—as it was during the 1600s and 1700s for prepubertal boys who were castrated to preserve their soprano voices for Italian opera—sex characteristics and sexual desire do not develop normally (Peschel & Peschel, 1987).
- . *In later life, sex hormone levels fall.* Women experience menopause as their estrogen levels decrease; males experience a more gradual change ([Chapter 4](#)). Sex remains a part of life, but as hormone levels decline, sexual fantasies and intercourse decline as well (Leitenberg & Henning, 1995).
- . *For some, surgery or drugs may cause hormonal shifts.* When adult men were castrated, their sex drive typically fell as testosterone levels declined sharply (Hucker & Bain, 1990). Male sex offenders who take a drug that reduces their testosterone levels to that of a prepubertal boy have similarly lost much of their sexual urge (Bilefsky, 2009; Money et al., 1983).

To summarize: We might compare human sex hormones, especially testosterone, to the fuel in a car. Without fuel, a car will not run. But if the fuel level is minimally adequate, adding more won't change how the car runs. The analogy is imperfect, because hormones and sexual motivation interact.

However, it correctly suggests that biology is a necessary but incomplete explanation of human sexual behavior. The hormonal fuel is essential, but so are the psychological stimuli that turn on the engine, keep it running, and shift it into high gear.

RETRIEVAL PRACTICE

RP-6 The primary male sex hormone is _____. The primary female sex hormones are the _____.

ANSWER: testosterone; estrogens

The Sexual Response Cycle

LOQ 11-6 What is the human *sexual response cycle*, and how do sexual dysfunctions and paraphilias differ?

The scientific process often begins with careful observations of complex behaviors. When gynecologist-obstetrician William Masters and his collaborator Virginia Johnson (1966) applied this process to human sexual intercourse in the 1960s, they made headlines. They recorded the physiological responses of volunteers who came to their lab to masturbate or have intercourse. With the help of 382 female and 312 male volunteers—a somewhat atypical sample, consisting only of people able and willing to display arousal and orgasm while scientists observed—Masters and Johnson reported observing more than 10,000 sexual “cycles.” Their description of the [sexual response cycle](#) identified four stages:

- . *Excitement*: The genital areas become engorged with blood, causing a woman’s clitoris and a man’s penis to swell. A woman’s vagina expands and secretes lubricant; her breasts and nipples may enlarge.
- . *Plateau*: Excitement peaks as breathing, pulse, and blood pressure rates continue to increase. A man’s penis becomes fully engorged—to an average length of 5.6 inches among 1661 men who measured themselves for condom fitting (Herbenick et al., 2014). Some fluid—frequently containing enough live sperm to enable conception—may appear at its tip. A woman’s vaginal secretion continues to increase, and her clitoris retracts. Orgasm

feels imminent.

- . **Orgasm:** Muscle contractions appear all over the body and are accompanied by further increases in breathing, pulse, and blood pressure rates. The pleasurable feeling of sexual release is much the same for both sexes. One panel of experts could not reliably distinguish between descriptions of orgasm written by men and those written by women (Vance & Wagner, 1976). In another study, PET scans showed that the same subcortical brain regions were active in men and women during orgasm (Holstege et al., 2003a,b).

A nonsmoking 50-year-old male has about a 1-in-a-million chance of a heart attack during any hour. This increases to merely 2-in-a-million in the two hours during and following sex (with no increase for those who exercise regularly). Compared with risks associated with heavy exertion or anger, this risk seems not worth losing sleep (or sex) over (Jackson, 2009; Muller et al., 1996).

- . **Resolution:** The body gradually returns to its unaroused state as the genital blood vessels release their accumulated blood. This happens relatively quickly if orgasm has occurred, relatively slowly otherwise. (It's like the nasal tickle that goes away rapidly if you have sneezed, slowly otherwise.) Men then enter a **refractory period** that lasts from a few minutes to a day or more, during which they are incapable of another orgasm. A woman's much shorter refractory period may enable her, if restimulated during or soon after resolution, to have more orgasms.

As you learned in [Chapter 2](#), there is also a *refractory period* in neural processing—the brief resting pause that occurs after a neuron has fired.

sexual response cycle the four stages of sexual responding described by Masters and Johnson—excitement, plateau, orgasm, and resolution.

refractory period in human sexuality, a resting period that occurs after

orgasm, during which a person cannot achieve another orgasm.

Sexual Dysfunctions and Paraphilias

Masters and Johnson sought not only to describe the human sexual response cycle but also to understand and treat the inability to complete it. **Sexual dysfunctions** are problems that consistently impair sexual arousal or functioning at any point in this cycle. Some involve sexual motivation, especially lack of sexual energy and arousability. For men, others include **erectile disorder** (inability to have or maintain an erection) and *premature ejaculation*. For women, the problem may be pain or **female orgasmic disorder** (distress over infrequently or never experiencing orgasm). In separate surveys of some 3000 Boston women and 32,000 other American women, about 4 in 10 reported a sexual problem, such as orgasmic disorder or low desire, but only about 1 in 8 reported that this caused personal distress (Lutfey et al., 2009; Shifren et al., 2008). Most women who have experienced sexual distress have related it to their emotional relationship with their partner during sex (Bancroft et al., 2003).

sexual dysfunction a problem that consistently impairs sexual arousal or functioning at any point in the sexual response cycle.

erectile disorder inability to develop or maintain an erection due to insufficient bloodflow to the penis.

female orgasmic disorder distress due to infrequently or never experiencing orgasm.

Psychological and medical therapies can help men and women with sexual dysfunctions (Frühauf et al., 2013). In behaviorally oriented therapy, for example, men learn ways to control their urge to ejaculate, and women are trained to bring themselves to orgasm. Starting with the introduction of Viagra in 1998, erectile disorder has been routinely treated by taking a pill. Some modestly effective drug treatments for *female sexual interest/arousal disorder* are also available.

Sexual dysfunction involves problems with arousal or sexual functioning. People with **paraphilias** (mostly men) do experience sexual desire, but they direct it in unusual ways (Baur et al., 2016). The American Psychiatric Association (2013) only classifies such behavior as disordered if

paraphilias sexual arousal from fantasies, behaviors, or urges involving nonhuman objects, the suffering of self or others, and/or nonconsenting persons.

- a person experiences distress from an unusual sexual interest *or*
- it entails harm or risk of harm to others.

The serial killer Jeffrey Dahmer had *necrophilia*, a sexual attraction to corpses. Those with *exhibitionism* derive pleasure from exposing themselves sexually to others, without consent. People with the paraphilic disorder *pedophilia* experience sexual arousal toward children who haven't entered puberty.

RETRIEVAL PRACTICE

RP-7 Someone who is distressed by impaired sexual arousal may be diagnosed with a _____.
Exhibitionism would be considered a _____.

ANSWER: sexual dysfunction; paraphilia

Sexually Transmitted Infections

LOQ 11-7 How can sexually transmitted infections be prevented?

Every day, more than 1 million people worldwide acquire a *sexually transmitted infection* (STI; also called *STD*, for *sexually transmitted disease*) (WHO, 2013b). “Compared with older adults,” reports the Centers for Disease Control (CDC, 2016b), “sexually active adolescents aged 15–19 years and young adults aged 20–24 years are at higher risk.” Teenage girls,

for example, are at heightened risk given their not fully mature anatomy and lower levels of protective antibodies (Dehne & Riedner, 2005; Guttmacher Institute, 1994).

Condoms offer only limited protection against certain skin-to-skin STIs, such as herpes, but they do reduce other risks (NIH, 2001). The effects were clear when Thailand promoted condom use by commercial sex workers. Over a four-year period, as condom use soared from 14 to 94 percent, the annual number of bacterial STIs plummeted from 410,406 to 27,362 (WHO, 2000). When used by people with an infected partner, condoms also have been 80 percent effective in preventing transmission of *HIV* (*human immunodeficiency virus*—the virus that causes [AIDS](#)) (Weller & Davis-Beaty, 2002; WHO, 2003). Although HIV can be transmitted by other means, such as needle sharing during drug use, its sexual transmission is most common. Half of all humans with HIV (and one fourth of Americans with HIV) are women. Because the virus is spread more easily from men to women, women's proportion of the worldwide AIDS population is growing.

AIDS (acquired immune deficiency syndrome) a life-threatening, sexually transmitted infection caused by the *human immunodeficiency virus* (HIV). AIDS depletes the immune system, leaving the person vulnerable to infections.

Just over half of Americans with AIDS are between ages 30 and 49 (CDC, 2013). AIDS' long incubation period means that many were infected in their teens and twenties. In 2012, the death of 1.6 million people with AIDS worldwide left behind countless grief-stricken partners and millions of orphaned children (UNAIDS, 2013). In sub-Saharan Africa, home to two-thirds of those with HIV, medical treatment to extend life and care for the dying is sapping needed resources.

Having sex with one person means also partnering with that person's past partners—any one of whom might have unknowingly transmitted an STI. Hence, the first step in preventing STIs is knowing one's status, and sharing it with one's partner.

The Psychology of Sex

LOQ 11-8 How do external and imagined stimuli contribute to sexual arousal?

Biological factors powerfully influence our sexual motivation and behavior. Yet the wide variations over time, across place, and among individuals document the great influence of psychological factors as well (**FIGURE 11.7**). Thus, despite the shared biology that underlies sexual motivation, the 281 (by one count) expressed reasons for having sex ranged widely—from “to get closer to God” to “to get my boyfriend to shut up” (Buss, 2008; Meston & Buss, 2007).

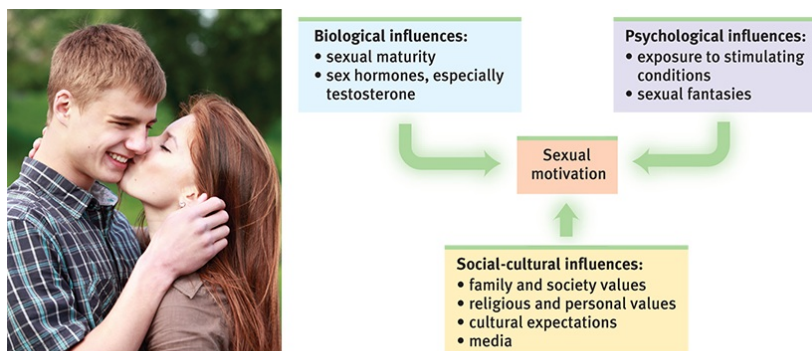

FIGURE 11.7 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Petrenko Andriy/Shutterstock

FIGURE 11.7 Biopsychosocial influences on sexual motivation

Compared with our motivation for eating, our sexual motivation is less influenced by biological factors. Psychological and social-cultural factors play a bigger role.

External Stimuli

Men and women become aroused when they see, hear, or read erotic material (Heiman, 1975; Stockton & Murnen, 1992). In men more than in women, *feelings* of sexual arousal closely mirror their (more obvious) physical genital responses (Chivers et al., 2010).

People may find sexual arousal either pleasing or disturbing. (Those who wish to control their arousal often limit their exposure to arousing materials, just as those wishing to avoid overeating limit their exposure to tempting food cues.) With repeated exposure to any stimulus, including an erotic stimulus, the emotional response lessens, or *habituates*. During the 1920s, when Western women’s hemlines rose to the knee, an exposed leg made

hearts flutter. Today, many would barely notice.

Can exposure to sexually explicit material have adverse effects? Research indicates that it can, in three ways.

- *Believing rape is acceptable* Depictions of women being sexually coerced—and appearing to enjoy it—have increased viewers’ belief in the false idea that women want to be overpowered, and have increased male viewers’ expressed willingness to hurt women and to commit rape after viewing such scenes (Allen et al., 1995, 2000; Foubert et al., 2011; Zillmann, 1989).
- *Reducing satisfaction with a partner’s appearance or with a relationship* After viewing images or erotic films of sexually attractive women and men, people have judged an average person, their own partner, or their spouse as less attractive. And they have found their own relationship less satisfying (Kenrick & Gutierrez, 1980; Lambert et al., 2012). Perhaps reading or watching erotica’s unlikely scenarios creates expectations that few men and women can fulfill.
- *Desensitization* Some studies have found that extensive online pornography exposure desensitizes young men to normal sexuality, thus contributing to erectile problems, lowered sexual desire, and diminished brain activation in response to sexual images. “Porn is messing with your manhood,” argue Philip Zimbardo and colleagues (2016). In one brain imaging study, men who frequently watched pornography had smaller-sized brain regions that aid sexual pleasure (Kühn & Gallinat, 2014).

Imagined Stimuli

The brain, it has been said, is our most significant sex organ. The stimuli inside our heads—our imagination—can influence sexual arousal and desire. Lacking genital sensation because of a spinal-cord injury, people can still feel sexual desire (Willmuth, 1987).

Both men and women (about 95 percent of each) report having sexual fantasies, which for a few women can, by themselves, produce orgasms (Komisaruk & Whipple, 2011). Men, regardless of sexual orientation, tend to have more frequent, more physical, and less romantic fantasies (Schmitt et al., 2012). They also prefer less personal and faster-paced sexual content in

books and videos (Leitenberg & Henning, 1995). Fantasizing about sex does *not* indicate a sexual problem or dissatisfaction. If anything, sexually active people have more sexual fantasies.

RETRIEVAL PRACTICE

RP-8 What factors influence our sexual motivation and behavior?

ANSWER: Influences include biological factors such as sexual maturity and sex hormones, psychological factors such as environmental stimuli and fantasies, and social-cultural factors such as the values and expectations absorbed from family and the surrounding culture.

Sexual Risk Taking and Teen Pregnancy

LOQ 11-9 What factors influence teenagers' sexual behaviors and use of contraceptives?

Sexual attitudes and behaviors vary dramatically across cultures and eras. “Sex between unmarried adults” is “morally unacceptable,” agree 97 percent of Indonesians and 6 percent of Germans (Pew, 2014b). And thanks to decreased sexual activity and increased protection, American teen pregnancy rates are declining (CDC, 2016b; Twenge et al., 2016b).

So, what produces variations in teen sexuality? Twin studies show that genes influence teen sexual behavior—by influencing pubertal development and hormone levels. But what environmental factors contribute?

COMMUNICATION ABOUT BIRTH CONTROL Many teenagers are uncomfortable discussing contraception with parents, partners, and peers. But teens who talk freely and openly with their parents and with their partner in an exclusive relationship are more likely to use contraceptives (Aspy et al., 2007; Milan & Kilmann, 1987).

IMPULSIVITY Among sexually active 12- to 17-year-old American girls, 72 percent said they regretted having had sex (Reuters, 2000). If passion overwhelms intentions (either to use contraceptives or to delay having sex), unplanned sexual activity may result in pregnancy (Ariely & Loewenstein, 2006; MacDonald & Hynie, 2008).

ALCOHOL USE Among late teens and young adults, most sexual hook-ups (casual encounters outside of a relationship) occur after alcohol use, often without knowing consent (Fielder et al., 2013; Garcia et al., 2013; Johnson & Chen, 2015). Those who use alcohol prior to sex are less likely to use condoms (Kotchick et al., 2001). By depressing the brain centers that control judgment, inhibition, and self-awareness, alcohol disarms normal restraints—a phenomenon well known to sexually coercive people.

“Condoms should be used on every conceivable occasion.”

Anonymous

MASS MEDIA Perceived peer norms influence teens' sexual behavior

(Lyons et al., 2015; van de Bongardt et al., 2015). Teens pay attention to other teens, who, in turn, are influenced by popular media. Media help write the *social scripts* that affect our perceptions and actions. The more sexual content adolescents and young adults view or read (even when controlling for other predictors of early sexual activity), the more likely they are to perceive their peers as sexually active, to develop sexually permissive attitudes, and to experience early intercourse (Escobar-Chaves et al., 2005; Kim & Ward, 2012; Parkes et al., 2013). One study asked more than a thousand 12- to 14-year-olds what movies they had seen, and then after age 18 asked them about their sexual experiences (O'Hara et al., 2012). After controlling for various adolescent and family characteristics, the more the adolescents viewed movies with high sexual content, the greater was their sexual risk taking—with earlier first sex, more partners, and inconsistent condom use.

Several factors predict sexual restraint:

- *High intelligence* Teens with high rather than average intelligence test scores more often delayed sex, partly because they considered possible negative consequences and were more focused on future achievement than on here-and-now pleasures (Harden & Mendle, 2011).
- *Religious engagement* Actively religious teens more often reserve sexual activity for adulthood or long-term relationships (Hull et al., 2011; Schmitt & Fuller, 2015; Stulhofer et al., 2011).
- *Father presence* In studies that followed hundreds of New Zealand and U.S. girls from age 5 to 18, having Dad around has reduced the risk of teen pregnancy and of sexual activity before age 16 (Ellis et al., 2003). These associations held even after adjusting for other influences, such as poverty. Close family attachments—as in families that eat together and where parents know their teens' activities and friends—also predict later sexual initiation (Coley et al., 2008).
- *Service learning participation* Several experiments have found that teens volunteering as tutors or teachers' aides, or participating in community projects, had lower pregnancy rates than did comparable teens randomly assigned to control conditions (Kirby, 2002; O'Donnell et al., 2002). Researchers are unsure why. Does service learning promote a sense of personal competence, control, and responsibility? Does it encourage more future-oriented thinking? Or does it simply reduce opportunities for unprotected sex? (Later school start times and after-school activities also

reduced unplanned pregnancies [Bryan et al., 2016; Steinberg, 2015].)

dpa/picture-alliance/Newscom

Keeping abreast of hypersexuality

An analysis of the 60 top-selling video games found 489 characters, 86 percent of whom were males (like most of the game players). The female characters were much more likely than the male characters to be “hypersexualized”—partially nude or revealingly clothed, with large breasts and tiny waists (Downs & Smith, 2010). Such depictions can lead to unrealistic expectations about sexuality and contribute to the early sexualization of girls. The American Psychological Association suggests countering this by teaching girls to “value themselves for who they are rather than how they look” (APA, 2007).

Father presence

RETRIEVAL PRACTICE

RP-9 Which THREE of the following five factors contribute to unplanned teen pregnancies?

- a. Alcohol use
- b. Higher intelligence level
- c. Father absence
- d. Mass media models
- e. Participating in service learning programs

ANSWER: a, c, d

Sexual Orientation

LOQ 11-10 What has research taught us about sexual orientation?

To motivate is to energize and direct behavior. So far, we have considered the energizing of sexual motivation but not its direction, which is our **sexual orientation**—our enduring sexual attraction toward members of our own sex (*homosexual orientation*), the other sex (*heterosexual orientation*), or both sexes (*bisexual orientation*). Most people fall into one of the first two categories (Norris et al., 2015). We experience this attraction in our interests, thoughts, and fantasies (who's that person in your imagination?).

sexual orientation an enduring sexual attraction toward members of one's own sex (homosexual orientation), the other sex (heterosexual orientation), or both sexes (bisexual orientation).

Cultures vary in their attitudes toward same-sex attractions. “Should society accept homosexuality?” Yes, say 88 percent of Spaniards and 1 percent of Nigerians, with women everywhere being more accepting than men (Pew, 2013b). Yet whether a culture condemns or accepts same-sex unions, heterosexuality prevails and bisexuality and homosexuality exist. In most African countries, same-sex relationships are illegal. Yet the ratio of lesbian, gay, or bisexual people “is no different from other countries in the rest of the world,” reports the Academy of Science of South Africa (2015). What is more, same-sex activity spans human history.

As explained in [Chapter 4](#), sexual orientation is distinct from *gender identity* (including *transgender* identity).

How many people are exclusively homosexual? According to more than a dozen national surveys in Europe and the United States, about 3 or 4 percent of men and 2 percent of women (Chandra et al., 2011; Herbenick et al., 2010; Savin-Williams et al., 2012). When the U.S. National Center for Health Statistics asked 34,557 Americans about their sexual identity, they found that all but 3.4 percent answered “straight,” with 1.6 percent answering “gay” or “lesbian” and 0.7 percent saying “bisexual” (Ward et al., 2014). In a follow-up survey, 1.6 percent of women and 2.3 percent of men anonymously reported feeling “mostly” or “only” same-sex attraction (Copen et al., 2016). A larger number of adults—13 percent of women and 5 percent of men—report some same-sex sexual contact during their lives (Chandra et al., 2011).

In less tolerant places, people are more likely to hide their sexual orientation. About 3 percent of California men express a same-sex preference on Facebook, for example, as do only about 1 percent in Mississippi. Yet about 5 percent of Google pornography searches in both states are for gay porn. And Craigslist ads for males seeking “casual encounters” with other men tend to be at least as common in less tolerant states, where there are also more Google searches for “gay sex” and “Is my husband gay?” (MacInnis &

Hodson, 2015; Stephens-Davidowitz, 2013).

What does it feel like to have same-sex attractions in a majority heterosexual culture? If you are heterosexual, imagine how you would feel if you were socially isolated for openly admitting or displaying your feelings. How would you react if you overheard people making crude jokes about heterosexual people, or if most movies, TV shows, and advertisements portrayed (or implied) homosexuality? And how would you answer if your family members were pleading with you to change your heterosexual “lifestyle” and to enter into a homosexual marriage?

Splash News/Newscom; STAN HONDA/Getty Images

Driven to suicide

In 2010, Rutgers University student Tyler Clementi jumped off this bridge after his roommate secretly filmed, shared, and tweeted about Clementi’s intimate encounter with another man. Reports then surfaced of other gay teens who had reacted in a similarly tragic fashion after being taunted. Since 2010, Americans—especially those under 30—have been increasingly supportive of those with same-sex orientations.

Facing such reactions, some individuals struggle with their sexual attractions, especially during adolescence and if feeling rejected by parents or harassed by peers. If lacking social support, nonheterosexual teens may have lower self-esteem, higher anxiety and depression, and an increased risk of contemplating suicide (Becker et al., 2014; Lyons, 2015; Wang et al., 2012, 2015b). They may at first try to ignore or deny their desires, hoping they will go away. But they don’t. They may try to change their orientation through

psychotherapy, willpower, or prayer. But the feelings typically persist, as do those of heterosexual people—who are similarly incapable of change (Haldeman, 1994, 2002; Myers & Scanzoni, 2005).

The prevalence of harmful anti-gay stereotypes can also contribute to the isolation and rejection that many nonheterosexual people feel. One such stereotype is that homosexual people are more likely to molest children (Herek, 2016). Is there any truth to this? *No*. Measuring men’s genital response to various sexual images indicates that sexual orientation is unrelated to pedophilia (Blanchard et al., 2009; Herek, 2016). A Canadian research team led by Ray Blanchard (2012; Dreger, 2011) outfitted 2278 men (mostly sex offenders) with a device that measured their sexual arousal when viewing nude photos of adults and children of both sexes, accompanied by sexual audio stories. Most of the men responded not to children, but to adult men (if gay) or to adult women (if straight). Some of the men—both straight and gay—exhibited pedophilia, by instead responding mostly to young boys or girls, and much less to adults. A simple summary: Some people are attracted to men; some people are attracted to women; fewer are attracted to both men and women; and fewer still exhibit a disordered attraction to children.

Today’s psychologists view sexual orientation as neither willfully chosen nor willfully changed. Sexual orientation in some ways is like handedness: Most people are one way, some the other. A very few are truly ambidextrous. Regardless, the way one is endures. “Efforts to change sexual orientation are unlikely to be successful and involve some risk of harm,” declared a 2009 American Psychological Association report. Recognizing this, in 2016, Malta became the first European country to outlaw the controversial practice of “conversion therapy,” which aims to change people’s *gender identities* or sexual orientations. Several U.S. states have likewise banned sexual conversion therapy with minors.

“There is no sound scientific evidence that sexual orientation can be changed.”

UK Royal College of Psychiatrists, 2009

Sexual orientation is especially persistent for men. Women’s sexual

orientation tends to be less strongly felt and, for some women, is more fluid and changing (Dickson et al., 2013; Norris et al., 2015). In general, men are sexually simpler. Men's lesser sexual variability is apparent in many ways (Baumeister, 2000). Across time, across cultures, across situations, and across differing levels of education, religious observance, and peer influence, men's sexual drive and interests are less flexible and varying than are adult women's. Women, for example, more often prefer to alternate periods of high sexual activity with periods of almost none (Mosher et al., 2005). Baumeister calls this flexibility *erotic plasticity*.

In men, a high sex drive is associated with increased attraction to women (if heterosexual) or men (if homosexual). In women, a high sex drive is generally associated with increased attraction to both men and women (Lippa, 2006, 2007; Lippa et al., 2010). When shown sexually explicit film clips, men's genital and subjective sexual arousal is mostly to preferred sexual stimuli (for heterosexual viewers, depictions of women). Women respond more nonspecifically to depictions of sexual activity involving males or females (Chivers et al., 2007; Huberman et al., 2015).

In one British survey of 18,876 people, and in other surveys since, about 1 percent acknowledge being asexual, having "never felt sexually attracted to anyone at all" (Bogaert, 2004, 2015). People identifying as asexual are, however, nearly as likely as others to report masturbating, noting that it feels good, reduces anxiety, or "cleans out the plumbing."

Origins of Sexual Orientation

So, our sexual orientation seems to be something we do not choose and (especially for males) cannot change. Where, then, do these preferences come from? See if you can anticipate the conclusions that have emerged from hundreds of research studies by responding *Yes* or *No* to the following questions:

- . Is homosexuality linked with a child's problematic relationships with parents, such as with a domineering mother and an ineffectual father, or a possessive mother and a hostile father?

- . Does homosexuality involve a fear or hatred of people of the other sex, leading individuals to direct their desires toward members of their own sex?
- . Is sexual orientation linked with sex hormone levels currently in the blood?
- . As children, were most homosexuals molested, seduced, or otherwise sexually victimized by an adult homosexual?

The answer to all these questions has been *No* (Storms, 1983). In a search for possible environmental influences on sexual orientation, Kinsey Institute investigators interviewed nearly 1000 homosexuals and 500 heterosexuals. They assessed nearly every imaginable psychological cause of homosexuality—parental relationships, childhood sexual experiences, peer relationships, dating experiences (Bell et al., 1981; Hammersmith, 1982). Their findings: Homosexuals are no more likely than heterosexuals to have been smothered by maternal love or neglected by their father. In one national survey of nearly 35,000 adults, those with a same-sex attraction were somewhat more likely to report having experienced child sexual abuse. But 86 percent of the men and 75 percent of the women with same-sex attraction reported no such abuse (Roberts et al., 2013).

And consider this: If “distant fathers” were more likely to produce homosexual sons, then shouldn’t boys growing up in father-absent homes more often be gay? (They are not.) And shouldn’t the rising number of such homes have led to a noticeable increase in the gay population? (It has not.) Most children raised by gay or lesbian parents grow up straight (Gartrell & Bos, 2010). And they grow up with normal health and emotional well-being (Bos et al., 2016).

Imagine that a mad scientist pitted nature against nurture by, at birth, changing a group of boys into girls—by castrating them, thus surgically feminizing them, and then raising them as girls. Surely this would socialize these “girls” into becoming attracted to males? In seven famous cases, this actually has happened, sometimes as a surgical procedure after the accidental severing of a penis during surgery. In each case, the result was a person attracted to *women*—just “the result we would expect if male sexual orientation were entirely due to nature,” concluded a consensus statement by sexual orientation experts (Bailey et al., 2016).

So, what else might influence sexual orientation? One theory has proposed that people develop same-sex erotic attachments if segregated by sex at the time their sex drive matures (Storms, 1981). Indeed, gay men tend to recall

going through puberty somewhat earlier, when peers are more likely to be all males (Bogaert et al., 2002). But even in tribal cultures in which homosexual behavior is expected of all boys before marriage, heterosexuality prevails (Hammack, 2005; Money, 1987). (As this illustrates, homosexual *behavior* does not always indicate a homosexual *orientation*.) Moreover, though peers' attitudes predict teens' sexual attitudes and behavior, they do not predict same-sex attraction. "Peer influence has little or no effect" on sexual orientation (Brakefield et al., 2014).

The bottom line from a half-century's theory and research: If there are environmental factors that influence sexual orientation after we're born, we do not yet know what they are. This reality has motivated researchers to explore same-sex behaviors in animals and to consider gay-straight brain differences, genetics, and prenatal influences.

SAME-SEX ATTRACTION IN OTHER SPECIES In Boston's Public Gardens, caretakers solved the mystery of why a much-loved swan couple's eggs never hatched. Both swans were female. In New York City's Central Park Zoo, penguins Silo and Roy spent several years as devoted same-sex partners. Same-sex sexual behaviors have also been observed in several hundred other species, including grizzlies, gorillas, monkeys, flamingos, and owls (Bagemihl, 1999). Among rams, for example, some 7 to 10 percent display same-sex attraction by shunning ewes and seeking to mount other males (Perkins & Fitzgerald, 1997). Homosexual behavior seems a natural part of the animal world.

See the **Video: Naturalistic Observation** for a helpful tutorial animation.

Boston Globe/Getty Images

Juliet and Juliet

Boston's beloved swan couple, "Romeo and Juliet," were discovered actually to be, as are many other animal partners, a same-sex pair.

GAY-STRAIGHT BRAIN DIFFERENCES Researcher Simon LeVay (1991) studied sections of the hypothalamus taken from deceased heterosexual and homosexual people. As a gay scientist, LeVay wanted to do "something connected with my gay identity." To avoid biasing the results, he did a *blind study*, not knowing which donors were gay. For nine months he peered through his microscope at a cell cluster that varied in size among donors. Then, one morning, he broke the code: One cell cluster was reliably larger in heterosexual men than in women and homosexual men. "I was almost in a state of shock," LeVay said (1994). "I took a walk by myself on the cliffs over the ocean. I sat for half an hour just thinking what this might mean."

It should not surprise us that in other ways, too, brains differ with sexual orientation (Bao & Swaab, 2011; Savic & Lindström, 2008). Remember our maxim: *Everything psychological is simultaneously biological*. But when do such brain differences begin? At conception? In the womb? During childhood or adolescence? Does experience produce these differences? Or is it genes or prenatal hormones (or genes activating prenatal hormones)?

LeVay does not view the hypothalamus as a sexual orientation center; rather, he sees it as an important part of the neural pathway engaged in sexual behavior. He acknowledges that sexual behavior patterns may influence the brain's anatomy. In fish, birds, rats, and humans, brain structures vary with experience—including sexual experience, reports sex researcher Marc Breedlove (1997). But LeVay believes it more likely that brain anatomy influences sexual orientation. His hunch seems confirmed by the discovery of a similar hypothalamic difference between the male sheep that do and don't display same-sex attraction (Larkin et al., 2002; Roselli et al., 2002, 2004). Moreover, such differences seem to develop soon after birth, or perhaps even before birth (Rahman & Wilson, 2003).

Responses to hormone-derived sexual scents also point to a brain difference (Savic et al., 2005). When straight women were given a whiff of a scent derived from men's sweat, their hypothalamus activated in an area governing sexual arousal. Gay men's brains responded similarly to the men's scent. But straight men's brains showed the arousal response only to a female hormone derivative. Other studies of brain responses to sex-related sweat

odors and to pictures of male and female faces have found similar gay-straight differences, including differing responses between lesbians and straight women (Kranz & Ishai, 2006; Martins et al., 2005). Researcher Qazi Rahman (2015) sums it up: Compared with heterosexuals, “gay men appear, on average, more ‘female typical’ in brain pattern responses and lesbian women are somewhat more ‘male typical.’”

“Gay men simply don’t have the brain cells to be attracted to women.”

Simon LeVay, *The Sexual Brain*, 1993

GENETIC INFLUENCES Evidence indicates that “about a third of variation in sexual orientation is attributable to genetic influences” (Bailey et al., 2016). A same-sex orientation does have some tendency to run in families. And identical twins are somewhat more likely than fraternal twins to share a homosexual orientation (Alanko et al., 2010; Långström et al., 2010). Because sexual orientations differ in many identical twin pairs, especially female twins, we know that other factors besides genes are also at work—including, it appears, epigenetic marks that help distinguish gay and straight identical twins (Balter, 2015).

See the **Video: Twin Studies** for a helpful tutorial animation.

By genetic manipulations, experimenters have created female fruit flies that pursued other females during courtship, and males that pursued other males (Demir & Dickson, 2005). “We have shown that a single gene in the fruit fly is sufficient to determine all aspects of the flies’ sexual orientation and behavior,” explained Barry Dickson (2005). With humans, it’s likely that multiple genes, possibly in interaction with other influences, shape sexual orientation. A genome-wide study of 409 pairs of gay brothers identified sexual orientation links with areas of two chromosomes, one maternally transmitted (Sanders et al., 2015).

Researchers have speculated about possible reasons why “gay genes” might exist in the human gene pool, given that same-sex couples cannot naturally reproduce. One possible answer is kin selection. Recall from [Chapter 4](#) the evolutionary psychology reminder that many of our genes also reside in our biological relatives. Perhaps, then, gay people’s genes live on

through their supporting the survival and reproductive success of their nieces, nephews, and other relatives. Gay men make generous uncles, suggests one study of Samoans (Vasey & VanderLaan, 2010).

A *fertile females theory* suggests that maternal genetics may also be at work (Bocklandt et al., 2006). Italian studies confirm what others have found—that homosexual men tend to have more homosexual relatives on their mother’s side than on their father’s (Camperio-Ciani et al., 2004, 2009, 2012; VanderLaan & Vasey, 2011; VanderLaan et al., 2012). And the relatives on the mother’s side also produce more offspring than do the maternal relatives of heterosexual men. Perhaps the genes that dispose some women to conceive more children with men also dispose some men to be attracted to men (LeVay, 2011). Thus, the decreased reproduction by gay men appears offset by the increased reproduction by their maternal extended family.

PRENATAL INFLUENCES Elevated rates of homosexual orientation in identical *and* fraternal twins suggest an influence not only of shared genes but also a shared prenatal environment. Recall that in the womb, sex hormones direct our development as male or female. In animals and some human cases, prenatal hormone conditions have altered a fetus’ sexual orientation. German researcher Gunter Dorner (1976, 1988) pioneered research on the influence of prenatal hormones by manipulating a fetal rat’s exposure to male hormones, thereby “inverting” its sexual orientation. In other studies, when pregnant sheep were injected with testosterone during a critical period of fetal development, their female offspring later showed homosexual behavior (Money, 1987).

A critical period for the human brain’s neural-hormonal control system may exist during the second trimester (Ellis & Ames, 1987; Garcia-Falgueras & Swaab, 2010; Meyer-Bahlburg, 1995). Exposure to the hormone levels typically experienced by female fetuses during this time appears to predispose the person (whether female or male) to be attracted to males in later life. “Prenatal sex hormones control the sexual differentiation of brain centers involved in sexual behaviors,” notes Simon LeVay (2011, [p. 216](#)). Thus, female fetuses most exposed to testosterone, and male fetuses least exposed to testosterone, appear most likely later to exhibit gender-atypical traits and to experience same-sex desires.

“Modern scientific research indicates that sexual orientation is . . . partly determined by genetics, but more specifically by hormonal activity in the womb.”

Glenn Wilson and Qazi Rahman, *Born Gay: The Psychobiology of Sex Orientation*, 2005

The mother’s immune system may also play a role in the development of sexual orientation. Men with older brothers are somewhat more likely to be gay, report Ray Blanchard (2004, 2008a,b, 2014) and Anthony Bogaert (2003)—about one-third more likely for each additional older brother. If the odds of homosexuality are roughly 2 percent among first sons, they would rise to about 2.6 percent among second sons, 3.5 percent for third sons, and so on for each additional older brother (Bailey et al., 2016; see [FIGURE 11.8](#)).

FIGURE 11.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 11.8 The older brother effect

Researcher Ray Blanchard (2008a) offers these approximate curves depicting a man’s likelihood of homosexuality as a function of the number of biological (not adopted) older brothers he has. This correlation has been found in several studies, but only among right-handed men (as about 9 in 10 men are).

The reason for this curious phenomenon—the *older brother* or *fraternal birth-order effect*—is unclear. Blanchard suspects a defensive maternal immune response to foreign substances produced by male fetuses. With each pregnancy with a male fetus, the maternal antibodies may become stronger

and may prevent the fetus’ brain from developing in a male-typical pattern. Consistent with this biological explanation, the fraternal birth-order effect occurs only in men with older brothers born to the same mother (whether raised together or not). Sexual orientation is unaffected by adoptive brothers (Bogaert, 2006). The birth-order effect on sexual orientation is not found among women with older sisters, women who were womb-mates of twin brothers, and men who are not right-handed (Rose et al., 2002).

Note that the scientific question is not “What causes homosexuality?” (or “What causes heterosexuality?”) but “What causes differing sexual orientations?” In pursuit of answers, psychological science compares the backgrounds and physiology of people whose sexual orientations *differ*.

Gay-Straight Trait Differences

Comparing the traits of gay and straight people is akin to comparing the heights of men and women. The average man is taller than most women, but many women are taller than most men. And just as knowing someone’s height doesn’t specify their sex, so also knowing someone’s traits doesn’t tell you their sexual orientation. Yet on several traits, the average homosexual female or male is intermediate between straight females and males ([TABLE 11.3](#); see also LeVay, 2011; Rahman & Koerting, 2008; Rieger et al., 2016). For example, lesbians’ cochlea and hearing systems develop in a way that is intermediate between those of heterosexual females and heterosexual males, which seems attributable to prenatal hormonal influence (McFadden, 2002). From birth on, gay males tend to be shorter and lighter than straight males, while from birth on, lesbian females tend to be heavier than straight females (Bogaert, 2010; Deputy & Boehmer, 2014; Frisch & Zdravkovic, 2010). Facial structure and fingerprint ridge counts may also differ (Hall & Kimura, 1994; Mustanski et al., 2002; Sanders et al., 2002; Skorska et al., 2015).

TABLE 11.3
Biological Correlates of Sexual Orientation

--

Gay-straight trait differences

Sexual orientation is part of a package of traits. Studies—some in need of replication—indicate that homosexuals and heterosexuals differ in the following biological and behavioral traits:

- spatial abilities
- fingerprint ridge counts
- auditory system development
- handedness
- occupational preferences
- relative finger lengths
- gender nonconformity
- age of onset of puberty in males
- face structure and birth size/weight
- sleep length
- physical aggression
- walking style

On average (the evidence is strongest for males), results for gays and lesbians fall between those of straight men and straight women. Three biological influences—brain, genetic, and prenatal—may contribute to these differences.

Brain differences

- One hypothalamic cell cluster is smaller in women and gay men than in straight men.
- Gay men's hypothalamus reacts as does straight women's to the smell of men's sex-related hormones.

Genetic influences

- Shared sexual orientation is higher among identical twins than among fraternal twins.
- Sexual attraction in fruit flies can be genetically manipulated.
- Male homosexuality often appears to be transmitted from the mother's side of the family.

Prenatal influences

- Altered prenatal hormone exposure may lead to homosexuality in humans and other animals.
- Men with several older biological brothers are more likely to be gay, possibly due to a maternal immune-system reaction.

For an 8-minute overview of the biology of sexual orientation, see the **Video: Homosexuality and the Nature-Nurture Debate**.

Another you-never-would-have-guessed-it gay-straight difference appears in studies showing that gay men's spatial abilities resemble those typical of straight women (Cohen, 2002; Gladue, 1994; McCormick & Witelson, 1991; Sanders & Wright, 1997). On mental rotation tasks such as the one illustrated in [FIGURE 11.9](#), straight men tend to outscore straight women. (So do women who were womb-mates of a male co-twin [Vuoksima et al., 2010].) Studies by Qazi Rahman and colleagues (2004, 2008) find that, as on a number of other measures, the scores of gays and lesbians fall between those of heterosexual males and females. But straight women and gays have both outperformed straight men at remembering objects' spatial locations in memory game tasks (Hassan & Rahman, 2007).

* * *

FIGURE 11.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 11.9 Spatial abilities and sexual orientation

Which of the three figures can be rotated to match the Original figure at the top? Straight males tend to find this type of mental rotation task easier than do straight females, with gays and lesbians falling in between (Rahman et al., 2004).¹

The consistency of the brain, genetic, and prenatal findings has swung the pendulum toward a biological explanation of sexual orientation (Rahman & Wilson, 2003; Rahman & Koerting, 2008). Still, some people wonder: Should the cause of sexual orientation matter? Perhaps it shouldn't, but people's assumptions matter. If you see sexual orientation as inborn—as shaped by biological and prenatal influences—then you likely favor “equal rights for homosexual and bisexual people” (Bailey et al., 2016). If you see same-sex attraction as a lifestyle choice or as encouraged by social tolerance, then you likely oppose equal rights for nonheterosexual people. To justify his signing a 2014 bill that made some homosexual acts punishable by life in prison, the president of Uganda, Yoweri Museveni, declared that homosexuality is not inborn but rather is a matter of “choice” (Balter, 2014; Landau, E., et al., 2014).

However, the new biological research is a double-edged sword (Roan, 2010). If sexual orientation, like skin color and sex, is genetically influenced, that offers a rationale for civil rights protection—though not the only rationale, argue rights advocates (Diamond & Rosky, 2016). Yet this research raises the troubling possibility that genetic markers of sexual orientation could someday be identified through fetal testing, that a fetus could be aborted simply for being predisposed to an unwanted orientation, or that hormonal treatment in the womb might engineer a desired orientation.

RETRIEVAL PRACTICE

RP-10 Which THREE of the following five factors have researchers found to have an effect on sexual orientation?

- a. A domineering mother
- b. The size of a certain cell cluster in the hypothalamus
- c. Prenatal hormone exposure
- d. A distant or ineffectual father
- e. For right-handed men, having multiple older biological brothers

ANSWER: b, c, e

Sex and Human Relationships

LOQ 11-11 What role do social factors play in our sexuality?

Scientific research on sexual motivation does not aim to define the personal meaning of sex in our own lives. You could know every available fact about sex—that the initial spasms of male and female orgasm come at 0.8-second intervals, that female nipples expand 10 millimeters at the peak of sexual arousal, that systolic blood pressure rises some 60 points and respiration rate reaches 40 breaths per minute—but fail to understand the human significance of sexual intimacy.

Surely one significance of such intimacy is its expression of our profoundly social nature. In one national study that followed participants to age 30, later first sex predicted greater satisfaction in one's marriage or partnership (Harden, 2012). Another study asked 2035 married people when they started having sex (while controlling for education, religious engagement, and relationship length). Those whose relationship first developed to a deep commitment, such as marriage, not only reported greater relationship satisfaction and stability but also better sex (Busby et al., 2010; Galinsky & Sonenstein, 2013). For both men and women, but especially for women, sex is more satisfying (with less regret and more orgasms) for those in a committed relationship, rather than a sexual hook-up (Armstrong et al., 2012; Garcia et al., 2012, 2013). Partners who share regular meals are more

likely than one-time dinner companions to understand what seasoning touches suit each other's food tastes; so, too, with the touches of loyal partners who share a bed.

The benefits of commitment—of “vow power”—apply regardless of sexual orientation. Gay and straight couples experience almost identical stability in their relationships, *if* they have married or entered into a civil union—and almost identical instability, if they have not (Rosenfeld, 2014). Thus, as the opportunity for straight and gay people to marry becomes more equal, we can expect the stability of their relationships to become more similar.

Sex is a socially significant act. Men and women can achieve orgasm alone, yet most people find greater satisfaction—and experience a much greater surge in the *prolactin* hormone associated with sexual satisfaction and satiety—after intercourse and orgasm with their loved one (Brody & Tillmann, 2006). Thanks to their overlapping brain reward areas, sexual desire and love feed each other (Cacioppo et al., 2012). Sex at its human best is life uniting and love renewing.

Increased sex ≠ more happiness

Among married couples, more frequent sex correlates with happiness. So, would systematically increasing sexual frequency *cause* people to be happier? Alas, heterosexual married couples randomly assigned to double their intercourse frequency over three months became slightly *less* happy (Loewenstein et al., 2015).

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively

thanks to the *testing effect*.

A striking effect of hormonal changes on human sexual behavior is the

- a. end of sexual desire in men over 60.
- b. sharp rise in sexual interest at puberty.
- c. decrease in women's sexual desire at the time of ovulation.
- d. increase in testosterone levels in castrated males.

In describing the sexual response cycle, Masters and Johnson noted that

- a. a plateau phase follows orgasm.
- b. people experience a refractory period during which they cannot experience orgasm.
- c. the feeling that accompanies orgasm is stronger in men than in women.
- d. testosterone is released equally in women and men.

What is the difference between sexual dysfunctions and paraphilias?

Using condoms during sex _____ (does/doesn't) reduce the risk of getting HIV and _____ (does/doesn't) fully protect against skin-to-skin STIs.

An example of an external stimulus that might influence sexual behavior is

- a. the level of testosterone in the bloodstream.
- b. the onset of puberty.
- c. a sexually explicit film.
- d. an erotic fantasy or dream.

Affiliation and Achievement

The Need to Belong

LOQ 11-12 What evidence points to our human affiliation need—our need to belong?

Separated from friends or family—alone in prison or at a new school or in a foreign land—most people feel keenly their lost connections with important others. We are what the ancient Greek philosopher Aristotle called *the social animal*. “Without friends,” wrote Aristotle in his *Nichomachean Ethics*, “no one would choose to live, though he had all other goods.” This deep *need to belong*—our [affiliation need](#)—seems a key human motivation (Baumeister & Leary, 1995). Mark Zuckerberg (2012) understands this, noting that he founded Facebook “to accomplish a social mission—to make the world more open and connected.” Although people vary in their wish for privacy and solitude, most of us seek to affiliate—to become strongly attached to certain others in enduring, close relationships. Human beings, contended personality theorist Alfred Adler, have an “urge to community” (Ferguson, 1989, 2001, 2010).

affiliation need the need to build relationships and to feel part of a group.

The Benefits of Belonging

Social bonds boosted our early ancestors’ chances of survival. Adults who formed attachments were more likely to survive, to reproduce, and to co-nurture their offspring to maturity. Attachment bonds motivated caregivers to keep children close, calming them and protecting them from threats (Esposito et al., 2013). Indeed, to be “wretched” literally means, in its Middle English origin (*wrecched*), to be without kin nearby.

Cooperation also enhanced survival. In solo combat, our ancestors were not the toughest predators. But as hunters, they learned that six hands were better than two. As food gatherers, they gained protection from two-footed and four-footed enemies by traveling in groups. Those who felt a need to belong survived and reproduced most successfully, and their genes now predominate. Our innate need to belong drives us to befriend people who cooperate and to avoid those who exploit (Feinberg et al., 2014). People in every society on Earth belong to groups and prefer and favor “us” over “them.” Having a social identity—feeling part of a group—boosts people’s health and well-being (Allen et al., 2015; Greenaway et al., 2015, 2016).

Photodisc/Getty Images

Do you have close friends—people with whom you freely disclose your ups and downs? Having someone who rejoices with us over good news helps us feel better about both the news and the friendship (Reis et al., 2010). A stranger’s casual thank-you can warm our heart (Williams & Bartlett, 2015). And close friends can literally make us feel warm, as if we are holding a soothing cup of warm tea (Inagaki & Eisenberger, 2013). The need to belong runs deeper, it seems, than any need to be rich. One study found that very happy university students were distinguished not by their money but by their “rich and satisfying close relationships” (Diener & Seligman, 2002).

The need to belong colors our thoughts and emotions. We spend a great deal of time thinking about actual and hoped-for relationships. When relationships form, we often feel joy. Falling in mutual love, people have been known to feel their cheeks ache from their irrepressible grins. Asked,

“What is necessary for your happiness?” or “What is it that makes your life meaningful?” most people have mentioned—before anything else—close, satisfying relationships with family, friends, or romantic partners (Berscheid, 1985). Happiness hits close to home.

Consider: What was your most satisfying moment in the past week? Researchers asked that question of American and South Korean university students, then asked them to rate how much that moment had satisfied various needs (Sheldon et al., 2001). In both countries, the peak moment had satisfied self-esteem and relatedness-belonging needs. When we satisfy our need for relatedness in balance with two other basic psychological needs—*autonomy* (a sense of personal control) and *competence*—we experience a deep sense of well-being, our performance improves, and our self-esteem rides high (Cerasoli et al., 2016; Deci & Ryan, 2009; Milyavskaya et al., 2009). Indeed, *self-esteem* is a gauge of how valued and accepted we feel (Leary, 2012).

Small wonder, then, that our social behavior so often aims to increase our feelings of belonging. To gain acceptance, we generally conform to group standards. We wait in lines and obey laws. We monitor our behavior, hoping to make a good impression. We spend billions on clothes, cosmetics, and diet and fitness aids—all motivated by our search for love and acceptance.

Thrown together in groups at school, at work, or at camp, we form bonds. Parting, we feel distress. We promise to call, to write, to return for reunions. By drawing a sharp circle around “us,” the need to belong feeds both deep attachments to those inside the circle (loving families, faithful friendships, and team loyalty) and hostilities toward those outside (teen gangs, ethnic rivalries, and fanatic nationalism). Feelings of love activate brain reward and safety systems. In one experiment, deeply in love university students exposed to heat felt less pain when looking at their beloved’s picture (Younger et al., 2010). Pictures of our loved ones also activate a brain region—the prefrontal cortex—that dampens feelings of physical pain (Eisenberger et al., 2011). Love is a natural painkiller.

Even when bad relationships end, people suffer. In one 16-nation survey, and in repeated U.S. surveys, separated and divorced people have been half as likely as married people to say they are “very happy” (Inglehart, 1990; NORC, 2016a). Is that simply because happy people more often marry and stay married? A national study following British lives through time revealed

that, even after controlling for premarital life satisfaction, “the married are still more satisfied, suggesting a causal effect” of marriage (Grover & Helliwell, 2014). Divorce also predicts earlier mortality. Studies that have followed 6.5 million people in 11 countries reveal that, compared with married people, separated and divorced people are at greater risk for early death (Sbarra et al., 2011).

To improve your own relationships, try the online **Assess Your Strengths: How Strong Is Your Relationship, and How Might You Increase Its Strength?**

Children who move through a series of foster homes or through regular family relocations know the fear of being alone. After repeated disruption of budding attachments, they may have difficulty forming deep relationships (Oishi & Schimmack, 2010b). The evidence is clearest at the extremes. As we saw in [Chapter 5](#), children who grow up in institutions without a sense of belonging to anyone, or who are locked away at home and severely neglected tend to become withdrawn, frightened, even speechless.

No matter how secure our early years were, we all experience anxiety, loneliness, jealousy, or guilt when something threatens or dissolves our social ties. Much as life’s best moments occur when close relationships begin—making a new friend, falling in love, having a baby—life’s worst moments happen when close relationships end (Beam et al., 2016). Bereaved, we may feel life is empty or pointless, and we may overeat to fill that emptiness (Yang et al., 2016). Even the first months of living on a college campus can be distressing (English et al., 2017). But our need to belong pushes us to form new social connections (Oishi et al., 2013a).

For immigrants and refugees moving alone to new places, the stress and loneliness can be depressing. After years of placing individual families in isolated communities, U.S. immigration policies began to encourage *chain migration* (Pipher, 2002). The second Syrian refugee family settling in a town generally has an easier adjustment than the first.

Social isolation can put us at risk for mental decline and ill health (Cacioppo et al., 2015). Lonely older adults make more doctor visits and are at greater risk for dementia (Gerst-Emerson & Jayawardhana, 2015; Holwerda et al., 2014). But if feelings of acceptance and connection increase sufficiently, so will self-esteem, positive feelings, and physical health

(Blackhart et al., 2009; Holt-Lunstad et al., 2010; Smart Richman & Leary, 2009). A socially connected life is often a happy and healthy life.

VINCENT YU/AP Images

The need to connect

Six days a week, women from the Philippines work as domestic helpers in thousands of Hong Kong households. On Sundays, they throng to the central business district to picnic, dance, sing, talk, and laugh.

“Humanity could stage no greater display of happiness,” reported one observer (Economist, 2001).

To consider your own need to belong, try the online **Assess Your Strengths: How Strong Is Your Need to Belong, and How Can You Strengthen Your Feelings of Belonging?**

The Pain of Being Shut Out

Can you recall feeling excluded or ignored or shunned? Perhaps you were unfriended or ignored online. Perhaps others gave you the silent treatment, avoided you, looked away, mocked you, or shut you out in some other way. Or perhaps you have felt excluded when among people speaking an unfamiliar language (Dotan-Eliaz et al., 2009).

All these experiences are instances of [ostracism](#)—of social exclusion (Williams, 2007, 2009). Worldwide, humans use many forms of ostracism—exile, imprisonment, solitary confinement—to punish, and therefore control, social behavior. For children, even a brief time-out in isolation can be punishing. Asked to describe personal episodes that made them feel especially *bad* about themselves, people will—about four times in five—

describe a relationship difficulty (Pillemer et al., 2007).

ostracism deliberate social exclusion of individuals or groups.

The Granger Collection, NYC – All rights reserved.

Enduring the pain of ostracism

White cadets at the United States Military Academy at West Point ostracized Henry Flipper for years, hoping he would drop out. He persevered in spite of their cruelty and in 1877 became the first African-American West Point graduate.

“Just give me the death penalty, man.”

Paul Redd, from solitary confinement, 2015

Being shunned threatens one’s need to belong (Vanhalst et al., 2015; Wirth et al., 2010). “It’s the meanest thing you can do to someone, especially if you know they can’t fight back. I never should have been born,” said Lea, a lifelong victim of the silent treatment by her mother and grandmother. Like Lea, people often respond to ostracism with initial efforts to restore their acceptance, with depressed moods, and finally with withdrawal. Prisoner

William Blake (2013) has spent more than a quarter-century in solitary confinement. “I cannot fathom how dying any death could be harder and more terrible than living through all that I have been forced to endure,” he observed. To many, social exclusion is a sentence worse than death.

To experience ostracism is to experience real pain, as social psychologists Kipling Williams and his colleagues were surprised to discover in their studies of exclusion on social media (Gonsalkorale & Williams, 2006). (Perhaps you can recall the feeling of having few followers on a social networking site, or of having a text message or e-mail go unanswered.) Such ostracism, they discovered, takes a toll: It elicits increased activity in brain areas, such as the *anterior cingulate cortex*, that also respond to physical pain (Eisenberger, 2015; Rotge et al., 2015).

CBS Photo Archive/Getty Images

Social acceptance and rejection

Successful participants on the reality TV show Survivor form alliances and gain acceptance among their peers. The rest receive the ultimate social punishment as they are “voted off the island.”

When people view pictures of romantic partners who caused their hearts to break, their brains and bodies begin to ache (Kross et al., 2011). That helps explain another surprising finding: The pain reliever acetaminophen (as in Tylenol) lessens *social* as well as physical pain (DeWall et al., 2010). Across cultures, people use the same words (for example, *hurt*, *crushed*) for social pain and physical pain (MacDonald & Leary, 2005). Psychologically, we seem to experience social pain with the same emotional unpleasantness that marks physical pain.

Pain, whatever its source, focuses our attention and motivates corrective action. Rejected and unable to remedy the situation, people may relieve stress by seeking new friends, eating calorie-laden comfort foods, or strengthening their religious faith (Aydin et al., 2010; Maner et al., 2007; Sproesser et al., 2014). Or they may turn hostile. Ostracism breeds disagreeableness, which leads to further ostracism (Hales et al., 2016). In one series of experiments, researchers told some students (who had taken a personality test) that they were “the type likely to end up alone later in life,” or that people they had met didn’t want them in a group that was forming (Gaertner et al., 2008; Twenge et al., 2001).² They told other students that they would have “rewarding relationships throughout life,” or that “everyone chose you as someone they’d like to work with.” Those who were excluded became much more likely to engage in self-defeating behaviors and to act in disparaging or aggressive ways against those who had excluded them (blasting them with noise, for example). “If intelligent, well-adjusted, successful . . . students can turn aggressive in response to a small laboratory experience of social exclusion,” noted the research team, “it is disturbing to imagine the aggressive tendencies that might arise from . . . chronic exclusion from desired groups in actual social life.” Indeed, as Williams (2007) has observed, ostracism “weaves through case after case of school violence.”

“If no one turned around when we entered, answered when we spoke, or minded what we did, but if every person we met ‘cut us dead,’ and acted as if we were non-existing things, a kind of rage and impotent despair would ere long well up in us.”

William James, *Principles of Psychology*, 1890/1950, pp. 293–294

RETRIEVAL PRACTICE

RP-11 How have students reacted in studies where they were made to feel rejected and unwanted? What helps explain these results?

ANSWER: They engaged in more self-defeating behaviors and displayed more disparaging and aggressive behavior. These students’ basic *need to belong* seems to have been

disrupted.

Connecting and Social Networking

LOQ 11-13 How does social networking influence us?

As social creatures, we live for connection. Researcher George Vaillant (2013) was asked what he had learned from studying 238 Harvard University men from the 1930s to the end of their lives. He replied, “Happiness is love.” A South African Zulu saying captures the idea: *Umntu ngumuntu ngabantu* —“a person is a person through other persons.”

MOBILE NETWORKS AND SOCIAL MEDIA Look around and see humans connecting: talking, tweeting, texting, posting, chatting, social gaming, e-mailing. Walking across campus, you may see students glued to their phones, making little eye contact with passersby (or perhaps that’s you?). During mid-class breaks, do you observe students getting to know each other—or silently checking their phones, as one research team’s phone app counted students doing 56 times a day (Elias et al., 2016)? The changes in how we connect have been fast and vast.

- *Mobile phones:* At the end of 2016, 95 percent of the world’s 7.5 billion people lived in an area covered by a mobile-cellular network (ITU, 2016).
- *Texts:* The typical U.S. teen with a cell phone sends 30 texts a day (Lenhart, 2015b). Half of 18- to 29-year-olds with a smart phone check it multiple times per hour, and “can’t imagine . . . life without [it]” (Newport,

2015; Saad, 2015).

- *The Internet*: Worldwide in 2015, 68 percent of adults used the Internet (Poushter, 2016).
- *Social networking*: Among 2014's entering American college students, 94 percent were using social networking sites (Eagan et al., 2014). With one's friends online, it's hard not to be: Check in or miss out.

Image Source/SuperStock

THE NET RESULT: SOCIAL EFFECTS OF SOCIAL NETWORKING

By connecting like-minded people, the Internet serves as a social amplifier. In times of social crisis or personal stress, it provides information and supportive connections. It enables people to share their experiences and compare their lives with others, though it can be depressing when one garners few likes or has lots of bragging friends (Blease, 2015; Verduyn et al., 2015). The Internet also functions as an online matchmaker (as I [ND] can attest: I met my wife online). Dating websites aren't right for everyone, but they can effectively match partners who share desired characteristics (Bruch et al., 2016). As electronic communication has become an integral part of life, researchers continue to explore how it affects our relationships. Online networking is double-edged: Nature has designed us for face-to-face relationships, and those who spend hours online are *less* likely to know and draw help from their real-world neighbors. But it does help us connect with friends, stay in touch with extended family, and find support when facing challenges (Pew, 2009; Pinker, 2014; Rainie et al., 2011). When used in moderation, social networking predicts longer life (Hobbs et al., 2016).

"The women on these dating sites don't seem to believe I'm a prince."

Liam Francis Walsh The New Yorker
Collection/The Cartoon Bank

"Look, until there's a Tinder for pandas, we have to meet the old-fashioned way: being locked in a room together by scientists."

Alex Gregory The New Yorker Collection/
The CartoonBank

Does Electronic Communication Stimulate Healthy Self-

Disclosure? *Self-disclosure* is sharing ourselves—our joys, worries, and weaknesses—with others. Confiding can be a healthy way of coping with day-to-day challenges. When communicating electronically rather than face-to-face, we often are less focused on others' reactions. We are less self-conscious and thus less inhibited. Sometimes this is taken to an extreme, as when bullies hound a victim, hate groups post messages promoting bigotry or crimes, or teens send photos of themselves they later regret. More often, however, the increased self-disclosure serves to deepen friendships

(Valkenburg & Peter, 2009).

Does Social Networking Promote Narcissism? [Narcissism](#) is self-esteem gone wild. Narcissistic people are self-important, self-focused, and self-promoting. Personality tests may assess narcissism with items such as “I like to be the center of attention.” People with high narcissism test scores are especially active on social networking sites (Liu & Baumeister, 2016). They collect more superficial “friends.” They offer more staged, glamorous photos. They retaliate more against negative comments. And, not surprisingly, they *seem* more narcissistic to strangers (Buffardi & Campbell, 2008; Weiser, 2015).

narcissism excessive self-love and self-absorption.

For narcissists, social networking sites are more than a gathering place; they are a feeding trough. In one study, college students were *randomly assigned* either to edit and explain their online profiles for 15 minutes, or to use that time to study and explain a Google Maps routing (Freeman & Twenge, 2010). After completing their tasks, all were tested. Who then scored higher on a narcissism measure? Those who had spent the time focused on themselves.

See the **Video: Random Assignment** for a helpful tutorial animation.

MAINTAINING BALANCE AND FOCUS In both Taiwan and the United States, excessive online socializing and gaming have correlated with lower grades or increased anxiety and depression (Brooks, 2015; Lepp et al., 2014; Walsh et al., 2013). In one U.S. survey, 47 percent of the heaviest users of the Internet and other media were receiving mostly C grades or lower, as were just 23 percent of the lightest users (Kaiser Family Foundation, 2010). In another national survey, young adults who used seven or more social media platforms were three times more likely to be depressed or anxious than those who used two or fewer (Primack et al., 2016).

In today’s world, most of us are challenged to maintain a healthy balance between our real-world and online time. Experts offer some practical suggestions:

- *Monitor your time.* Keep a log of how you use your time. Then ask yourself, “Does my time use reflect my priorities? Am I spending more or less time online than I intended? Is my time online interfering with my school or work performance or relationships? Have family or friends commented on this?”
- *Monitor your feelings.* Ask yourself, “Am I emotionally distracted by my online interests? When I disconnect and move to another activity, how do I feel?”
- *“Hide” from your more distracting online friends when necessary.* And in your own postings, practice the golden rule: Ask yourself, “Is this something I’d care about if someone else posted it?”
- *When studying, get in the habit of checking your phone and e-mail less often.* Selective attention—the flashlight of your mind—can be in only one place at a time. When we try to do two things at once, we don’t do either one of them very well (Willingham, 2010). If you want to study or work productively, resist the temptation to always be available. Disable sound alerts, vibration, and pop-ups. In one experiment, randomly selected people who kept their e-mail closed and checked e-mail just three times a day enjoyed a significant reduction in stress (Kushlev & Dunn, 2015). (To avoid distraction, I [DM] am proofing and editing this chapter in a coffee shop without Wi-Fi.)
- *Refocus by taking a nature walk.* People learn better after a peaceful walk in a park, which—unlike a walk on a busy street—refreshes our capacity for focused attention (Berman et al., 2008). Connecting with nature boosts our spirits and sharpens our minds (Zelenski & Nisbet, 2014).

As psychologist Steven Pinker (2010) said, “The solution is not to bemoan technology but to develop strategies of self-control, as we do with every other temptation in life.”

"It keeps me from looking at my phone every two seconds."

Liam Francis Walsh The New Yorker
Collection/The Cartoon Bank

RETRIEVAL PRACTICE

RP-12 Social networking tends to (strengthen/weaken) your relationships with people you already know and (increase/decrease) your self-disclosure.

ANSWER: strengthen; increase

Achievement Motivation

LOQ 11-14 What is *achievement motivation*?

Some motives seem to have little obvious survival value. Billionaires may be motivated to make ever more money, reality TV stars to attract ever more social media followers, politicians to achieve ever more power, daredevils to seek ever greater thrills. Such motives seem not to diminish when they are fed. The more we achieve, the more we may need to achieve. Psychologist Henry Murray (1938) defined [achievement motivation](#) as a desire for significant accomplishment, for mastering skills or ideas, for control, and for attaining a high standard.

achievement motivation a desire for significant accomplishment; for mastery
--

of skills or ideas; for control; and for attaining a high standard.

Thanks to their persistence and eagerness for challenge, people with high achievement motivation do accomplish more. One famous study followed the lives of 1528 California children whose intelligence test scores were in the top 1 percent. Forty years later, when researchers compared those who were most and least successful professionally, they found a motivational difference. The most successful were more ambitious, energetic, and persistent. As children, they had more active hobbies. As adults, they participated in more groups and sports (Goleman, 1980). Gifted children are able learners. Accomplished adults are tenacious doers. Most of us are energetic doers when starting and when finishing a project. It's easiest—have you noticed?—to get stuck in the middle. That's when high achievers keep going (Bonezzi et al., 2011).

In some studies of both secondary school and university students, self-discipline has surpassed intelligence test scores in predicting school performance, attendance, and graduation honors. For school performance, “discipline outdoes talent,” concluded researchers Angela Duckworth and Martin Seligman (2005, 2006).

Discipline focuses and refines talent. By their early twenties, top violinists have accumulated thousands of lifetime practice hours—in fact, double the practice time of other violin students aiming to be teachers (Ericsson, 2001, 2006, 2007). A study of outstanding scholars, athletes, and artists found that all were highly motivated and self-disciplined, willing to dedicate hours every day to the pursuit of their goals (Bloom, 1985). But as young Mozart composing at age 8 illustrates, native talent matters, too (Hambrick & Meinz, 2011; Ruthsatz & Urbach, 2012). In sports, music, and chess, people's practice-time differences, while significant, account for a third or less of their performance differences (Hambrick et al., 2014a,b; Macnamara et al., 2014, 2016; Ullén et al., 2016). High achievers benefit from their passion and perseverance, but the superstars among them are also distinguished by their extraordinary natural talent.

Duckworth (2016) has a name for passionate dedication to an ambitious, long-term goal: **grit** (which other researchers have found similar to conscientiousness [Credé et al., 2016; Rimfeld et al., 2016]). When combined

with self-control (regulating one's attention and actions in the face of temptation), gritty goal-striving can produce great achievements. "If you want to look good in front of thousands," the saying goes, "you have to outwork thousands in front of nobody."

grit in psychology, passion and perseverance in the pursuit of long-term goals.

From Calum's Road by Roger Hutchinson,
reproduced courtesy of Birlinn Ltd.

Calum's road: What grit can accomplish

Having spent his life on the Scottish island of Raasay, farming a small patch of land, tending its lighthouse, and fishing, Malcolm ("Calum") MacLeod (1911–1988) felt anguished. His local government repeatedly refused to build a road that would enable vehicles to reach his north end of the island. With the once-flourishing population there having dwindled to two—MacLeod and his wife—he responded with heroic determination. One spring morning in 1964, MacLeod, then in his fifties, gathered an ax, a chopper, a shovel, and a wheelbarrow. By hand, he began to transform the existing footpath into a 1.75-mile road (Miers, 2009).

"With a road," a former neighbor explained, "he hoped new

generations of people would return to the north end of Raasay,” restoring its culture (Hutchinson, 2006). Day after day he worked through rough hillsides, along hazardous cliff faces, and over peat bogs. Finally, 10 years later, he completed his supreme achievement. The road, which the government has since surfaced, remains a visible example of what vision plus determined grit can accomplish. It bids us each to ponder: What “roads”—what achievements—might we, with sustained effort, build in the years before us?

Although intelligence is distributed like a bell curve, achievements are not. This tells us that achievement involves much more than raw ability. That is why smart parenting, teaching, and managing engages people’s *intrinsic* motivations to achieve (recall [Chapter 7](#)’s discussion of intrinsic versus extrinsic motivation). That is why organizational psychologists seek ways to motivate ordinary people doing ordinary jobs (see Appendix A: Psychology at Work). And that is why each of us can adopt some research-based strategies for achieving our goals:

- . *Do make that resolution.* Challenging goals motivate achievement (Harkin et al., 2016). Concrete goals—“finish the paper by Tuesday”—direct attention and motivate persistence.
- . *Announce the goal to friends or family.* We’re more likely to follow through after making a public commitment.
- . *Develop an implementation plan*—an action strategy that specifies when, where, and how we will progress toward our goal. People who flesh out goals with detailed plans become more focused and more likely to succeed (Gollwitzer & Oettingen, 2012). Better to center on small steps—the day’s running target—than to fantasize the marathon.
- . *Monitor and record progress*, perhaps aided by a tracker such as a Fitbit. All the better when that progress is displayed publicly rather than kept secret (Harkin et al., 2016).
- . *Create a supportive environment.* When trying to eat healthy, keep junk food out of the cupboards. Use small plates and bowls. When focusing on a project, hole up in the library. When sleeping, stash the phone. Such “situational self-control strategies” prevent tempting impulses (Duckworth et al., 2016).
- . *Transform the hard-to-do behavior into a must-do habit.* Habits form when we repeat behaviors in a given context ([Chapter 7](#)). As our behavior

becomes linked with the context, our next experience of that context evokes our habitual response. To increase our self-control, to connect our resolutions with positive outcomes, the key is forming “beneficial habits” (Galla & Duckworth, 2015). Do something every day for about two months and it will become an ingrained habit.

- . To achieve important life goals, we often know what to do. We *know* that a full night’s sleep boosts our alertness, energy, and mood. We *know* that exercise lessens depression and anxiety, sculpts our bodies, and strengthens our hearts and minds. We *know* that what we put into our bodies—junk food or balanced nutrition, addictive substances or clean air—affects our health and longevity. Alas, as T. S. Eliot foresaw, “Between the idea and the reality . . . Falls the Shadow.” Nevertheless, by taking these six steps—resolving, announcing, planning, monitoring, controlling, and persistently acting—we can create a bridge between the idea and the reality.

“Genius is 1% inspiration and 99% perspiration.”

Thomas Edison (1847–1931)

RETRIEVAL PRACTICE

RP-13 What have researchers found to be an even better predictor of school performance than intelligence test scores?

ANSWER: self-discipline (grit)

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Which of the following is NOT evidence supporting the view that humans are strongly motivated by a need to belong?

- a. Students who rated themselves as “very happy” also tended to have satisfying close relationships.
- b. Social exclusion—such as exile or solitary confinement—is considered a severe form of punishment.
- c. As adults, adopted children tend to resemble their biological parents.
- d. Children who are extremely neglected become withdrawn, frightened, and speechless.

What are some ways to manage our social networking time successfully?

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Coping With Stress

Reducing Stress

No one needs to tell you that feelings add color to your life, or that in times of stress they can disrupt your life, or save it. Fear, anger, sadness, joy, and love are psychological states that also entail physical reactions. Nervous about an important encounter, we feel stomach butterflies. Anxious over public speaking, we frequent the bathroom. Smoldering over a family conflict, we get a splitting headache.

You can surely recall a time when emotion overwhelmed you. I [DM] retain a flashbulb memory of the day I went to a huge store and brought along Peter, my toddler first-born child. As I set Peter down on his feet for a moment to do some paperwork, a passerby warned, “You’d better be careful or you’ll lose that boy!” Not more than a few breaths later, I turned and found no Peter beside me.

With mild anxiety, I peered around one end of the customer service counter. No Peter in sight. With slightly more anxiety, I peered around the other end. No Peter there, either. Now, with my heart accelerating, I circled the neighboring counters. Still no Peter anywhere. As anxiety turned to panic, I began racing up and down the store aisles. He was nowhere to be found. The alerted store manager used the public-address system to ask customers to assist in looking for a missing child. Soon after, I passed the customer who had warned me. “I told you that you were going to lose him!” he now scolded. With visions of kidnapping (strangers routinely adored that beautiful child), I braced for the unthinkable possibility that my negligence had caused me to lose what I loved above all else, and that I might have to return home and face my wife without our only child.

But then, as I passed the counter yet again, there he was, having been found and returned by some obliging customer. In an instant, the arousal of

terror spilled into ecstasy. Clutching my son, with tears suddenly flowing, I found myself unable to speak my thanks and stumbled out of the store awash in grateful joy.

Emotions are subjective. But they are real, says researcher Lisa Feldman Barrett (2012, 2013): “My experience of anger is not an illusion. When I’m angry, I feel angry. That’s real.” Where do our emotions come from? Why do we have them? What are they made of?

Emotions are our body’s adaptive response. They support our survival. When we face challenges, emotions focus our attention and energize our actions (Cyders & Smith, 2008). Our heart races. Our pace quickens. All our senses go on high alert. Receiving unexpected good news, we may find our eyes tearing up. We raise our hands triumphantly. We feel exuberance and a newfound confidence. Yet negative and prolonged emotions can harm our health.

Introduction to Emotion

Emotion: Arousal, Behavior, and Cognition

LOQ **LEARNING OBJECTIVE QUESTION** **12-1** How do arousal,

expressive behavior, and cognition interact in emotion?

As my [DM's] panicked search for Peter illustrates, [emotions](#) are a mix of

emotion a response of the whole organism, involving (1) physiological arousal, (2) expressive behaviors, and (3) conscious experience.

- *bodily arousal* (heart pounding),
- *expressive behaviors* (quicken pace), and
- *conscious experience* (“*Is this a kidnapping?*”) and feelings (panic, fear, joy).

Not only emotion, but most psychological phenomena (vision, sleep, memory, sex, and so forth) can be approached these three ways—physiologically, behaviorally, and cognitively.

The puzzle for psychologists is figuring out how these three pieces fit together. To do that, the first researchers of emotion considered two big questions:

- . A chicken-and-egg debate: Does your bodily arousal come *before* or *after* your emotional feelings? (Did I first notice my racing heart and faster step, and then feel terror about losing Peter? Or did my sense of fear come first, stirring my heart and legs to respond?)
- . How do *thinking* (cognition) and *feeling* interact? Does cognition always

come before emotion? (Did I think about a kidnapping threat before I reacted emotionally?)

Historical emotion theories, as well as current research, have sought to answer these questions.

Courtesy of David Myers

Historical Emotion Theories

The psychological study of emotion began with the first question: How do bodily responses relate to emotions? Two famous theories offered different answers.

JAMES-LANGE THEORY: AROUSAL COMES BEFORE EMOTION

Common sense tells most of us that we cry because we are sad, lash out because we are angry, tremble because we are afraid. First comes conscious awareness, then the feeling. But to pioneering psychologist William James, this commonsense view of emotion had things backward. Rather, “We feel sorry because we cry, angry because we strike, afraid because we tremble” (1890, p. 1066). To James, emotions result from attention to our bodily activity. James’ idea was also proposed by Danish physiologist Carl Lange, and so is called the [James-Lange theory](#). James and Lange would have guessed that I noticed my racing heart and then, shaking with fright, felt the whoosh of emotion—that my feeling of fear *followed* my body’s response.

James-Lange theory the theory that our experience of emotion is our awareness of our physiological responses to an emotion-arousing stimulus.

MATT SULLIVAN/REUTERS/Newscom

Joy expressed

According to the James-Lange theory, we don't just smile because we share our teammates' joy. We also share the joy because we are smiling with them.

CANNON-BARD THEORY: AROUSAL AND EMOTION OCCUR SIMULTANEOUSLY

Physiologist Walter Cannon (1871–1945) disagreed with the James-Lange theory. Does a racing heart signal fear or anger or love? The body's responses—heart rate, perspiration, and body temperature—are too similar, and they change too slowly, to *cause* the different emotions, said Cannon. He, and later another physiologist, Philip Bard, concluded that our bodily responses and experienced emotions occur separately but simultaneously. So, according to the [Cannon-Bard theory](#), my heart began pounding *as* I experienced fear. The emotion-triggering stimulus traveled to my sympathetic nervous system, causing my body's arousal. *At the same time*, it traveled to my brain's cortex, causing my awareness of my emotion. My pounding heart did not cause my feeling of fear, nor did my feeling of fear cause my pounding heart.

Cannon-Bard theory the theory that an emotion-arousing stimulus simultaneously triggers (1) physiological responses and (2) the subjective experience of emotion.

But are they really independent from each other? The Cannon-Bard theory has been challenged by studies of people with severed spinal cords, including a survey of 25 World War II soldiers (Hohmann, 1966). Those with *lower-spine injuries*, who had lost sensation only in their legs, reported little change in their emotions' intensity. Those with *high spinal cord injury*, who could feel nothing below the neck, did report changes. Some reactions were much less intense than before the injuries. Anger, one high spinal cord-injured man confessed, "just doesn't have the heat to it that it used to. It's a mental kind of anger." Other emotions, those expressed mostly in body areas above the neck, were felt more intensely. These men reported increases in weeping, lumps in the throat, and getting choked up when saying good-bye, worshiping, or watching a touching movie. Such evidence has led some researchers to view feelings as "mostly shadows" of our bodily responses and behaviors (Damasio, 2003). Brain activity underlies our emotions and our emotion-fed actions (Davidson & Begley, 2012).

But our emotions also involve cognition (Averill, 1993; Barrett, 2006). Here we arrive at psychology's second big emotion question: How do thinking and feeling interact? Whether we fear the man behind us on the dark street depends entirely on whether or not we interpret his actions as threatening.

RETRIEVAL PRACTICE

RP-1 According to the Cannon-Bard theory, (a) our *physiological response* to a stimulus (for example, a pounding heart), and (b) the *emotion we experience* (for example, fear) occur _____ (simultaneously/sequentially). According to the James-Lange theory, (a) and (b) occur _____ (simultaneously/sequentially).

ANSWER: simultaneously; sequentially (first the physiological response, and then the experienced emotion)

Schachter-Singer Two-Factor Theory: Arousal + Label = Emotion

LOQ 12-2 To experience emotions, must we consciously interpret and label them?

Stanley Schachter and Jerome Singer (1962) demonstrated that how we *appraise* our experiences also matters. Our physical reactions *and our thoughts* (perceptions, memories, and interpretations) together create emotion. In their [two-factor theory](#), emotions have two ingredients: physical arousal and cognitive appraisal. An emotional experience, they argued, requires a conscious interpretation of arousal.

two-factor theory the Schachter-Singer theory that to experience emotion one must (1) be physically aroused and (2) cognitively label the arousal.

Consider how arousal spills over from one event to the next. Imagine arriving home after an invigorating run and finding a message that you got a longed-for job. With arousal lingering from the run, would you feel more elated than if you heard this news after staying awake all night studying?

To explore this *spillover effect*, Schachter and Singer injected college men with the hormone epinephrine, which the trickster researchers told the men would help test their eyesight. In reality, the drug triggers feelings of arousal. Picture yourself as a participant: After receiving the injection, you go to a waiting room, where you find yourself with another person (actually an accomplice of the experimenters) who is acting either euphoric or irritated. As you observe this person, you begin to feel your heart race, your body flush, and your breathing become more rapid. If you had been told to expect these effects from the injection, what would you feel? The actual volunteers felt little emotion—because they attributed their arousal to the drug. But if you had been told the injection would produce no arousal, what would you feel? Perhaps you would react as another group of participants did. They “caught” the apparent emotion of the other person in the waiting room. They

became happy if the accomplice was acting euphoric, and testy if the accomplice was acting irritated.

OLEG POPOV/REUTERS/Newscom

The spillover effect

Arousal from a soccer match can fuel anger, which can descend into rioting or other violent confrontations.

This discovery—that a stirred-up state can be experienced as one emotion or another, depending on how we interpret and label it—has been replicated in dozens of experiments and continues to influence modern emotion research (MacCormack & Lindquist, 2016; Reisenzein, 1983; Sinclair et al., 1994). As researcher Daniel Gilbert (2006) noted, “Feelings that one interprets as fear in the presence of a sheer drop may be interpreted as lust in the presence of a sheer blouse.”

The point to remember: Arousal fuels emotion; cognition channels it.

For a 4-minute demonstration of the relationship between arousal and cognition, see the **Video: Emotion = Arousal Plus Interpretation**.

RETRIEVAL PRACTICE

RP-2 According to Schachter and Singer, two factors lead to our experience of an emotion: (1) physiological arousal and (2) _____ appraisal.

ANSWER: cognitive

Zajonc, LeDoux, and Lazarus: Does Cognition Always Precede Emotion?

But is the heart always subject to the mind? Must we *always* interpret our arousal before we can experience an emotion? Robert Zajonc [ZI-yence] (1923–2008) didn't think so. He contended that we actually have many emotional reactions apart from, or even before, our conscious interpretation of a situation (1980, 1984a). Perhaps you can recall liking something or someone immediately, without knowing why.

For example, when people repeatedly view stimuli flashed too briefly for them to interpret, they come to prefer those stimuli. Unaware of having previously seen them, they nevertheless like them. We have an acutely sensitive automatic radar for emotionally significant information, such that even a subliminally flashed stimulus can prime us to feel better or worse about a follow-up stimulus (Murphy et al., 1995; Zeelenberg et al., 2006).

Neuroscientists are charting the neural pathways of emotions (Ochsner et al., 2009). Our emotional responses can follow two different brain pathways. Some emotions (especially more complex feelings like hatred and love) travel a “high road.” A stimulus following this path would travel (by way of the thalamus) to the brain's cortex ([FIGURE 12.1a](#)). There, it would be analyzed and labeled before the response command is sent out, via the amygdala (an emotion-control center).

FIGURE 12.1 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.1 The brain's pathways for emotions

In the two-track brain, sensory input may be routed (a) to the cortex (via

the thalamus) for analysis and then transmission to the amygdala; or (b) directly to the amygdala (via the thalamus) for an instant emotional reaction.

But sometimes our emotions (especially simple likes, dislikes, and fears) take what Joseph LeDoux (2002, 2015) has called the “low road,” a neural shortcut that bypasses the cortex. Following the low road, a fear-provoking stimulus would travel from the eye or ear (again via the thalamus) directly to the amygdala ([Figure 12.1b](#)). This shortcut enables our greased-lightning emotional response before our intellect intervenes. Like speedy reflexes (that also operate separately from the brain’s thinking cortex), the amygdala reactions are so fast that we may be unaware of what’s transpired (Dimberg et al., 2000). A conscious feeling of fear then occurs as we become aware that our brain has detected danger.

The amygdala sends more neural projections up to the cortex than it receives back, which makes it easier for our feelings to hijack our thinking than for our thinking to rule our feelings (LeDoux & Armony, 1999). Thus, in the forest, we can jump at the sound of rustling bushes nearby, leaving it to our cortex to decide later whether the sound was made by a snake or by the wind. Such experiences support Zajonc’s and LeDoux’s belief that *some* of our emotional reactions involve no deliberate thinking.

Emotion researcher Richard Lazarus (1991, 1998) conceded that our brain processes vast amounts of information without our conscious awareness, and that some emotional responses do not require *conscious* thinking. Much of our emotional life operates via the automatic, speedy low road. But he wondered: How would we *know* what we are reacting to if we did not in some way appraise the situation? The appraisal may be effortless and we may not be conscious of it, but it is still a mental function. To know whether a stimulus is good or bad, the brain must have some idea of what it is (Storbeck et al., 2006). Thus, said Lazarus, emotions arise when we *appraise* an event as harmless or dangerous. We appraise the sound of the rustling bushes as the presence of a threat. Later, we realize that it was “just the wind.”

So, let’s sum up (see also [TABLE 12.1](#)). As Zajonc and LeDoux have demonstrated, some emotional responses—especially simple likes, dislikes, and fears—involve no conscious thinking ([FIGURE 12.2](#)). When I [ND] see a big spider trapped behind glass, I experience fear, even though I *know* the spider can’t hurt me. Such responses are difficult to alter by changing our

thinking. Within a fraction of a second, we may perceive one person as more likable or trustworthy than another (Willis & Todorov, 2006). This instant appeal can even influence our political decisions if we vote (as many people do) for a candidate we *like* over the candidate who expresses positions closer to our own (Westen, 2007).

TABLE 12.1
Summary of Emotion Theories

Theory	Explanation of Emotions	Example
<i>James-Lange</i>	Emotions arise from our awareness of our specific bodily responses to emotion-arousing stimuli.	We observe our heart racing after a threat and then feel afraid.
<i>Cannon-Bard</i>	Emotion-arousing stimuli trigger our bodily responses and simultaneous subjective experience.	Our heart races at the same time that we feel afraid.
<i>Schachter-Singer</i>	Our experience of emotion depends on two factors: general arousal and a conscious cognitive label.	We may interpret our arousal as fear or excitement, depending on the context.
<i>Zajonc; LeDoux</i>	Some embodied responses happen instantly, without conscious appraisal.	We automatically feel startled by a sound in the forest before labeling it as a threat.
<i>Lazarus</i>	Cognitive appraisal ("Is it dangerous or	The sound is "just the wind."

not?”)—sometimes without our awareness—defines emotion.

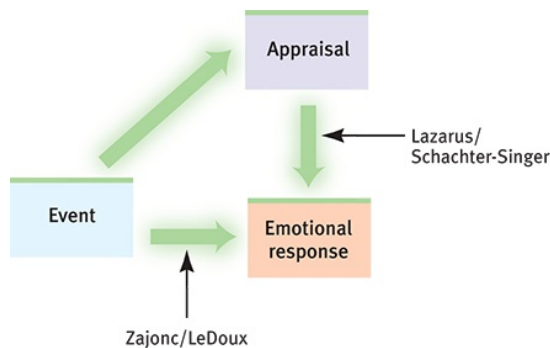

FIGURE 12.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.2 Two pathways for emotions

Zajonc and LeDoux emphasized that some emotional responses are immediate, before any conscious appraisal. Lazarus, Schachter, and Singer emphasized that our appraisal and labeling of events also determine our emotional responses.

But other emotions—including depressive moods and complex feelings such as hatred and love—are greatly affected by our conscious and unconscious information processing: our memories, expectations, and interpretations. For these emotions, we have more conscious control. When we feel emotionally overwhelmed, we can change our interpretations (Gross, 2013). Such *reappraisal* often reduces distress and the corresponding amygdala response (Buhle et al., 2014; Denny et al., 2015). Reappraisal not only reduces stress, it also helps students achieve higher exam scores (Jamieson et al., 2016). Don’t stress about your stress. Embrace it, and approach your next exam with the mindset, “Stress evolved to help maintain my focus and solve problems.” Although the emotional low road functions automatically, the thinking high road allows us to retake some control over our emotional life. *The bottom line:* Together, automatic emotion and conscious thinking weave the fabric of our emotional lives.

RETRIEVAL PRACTICE

RP-1 Emotion researchers have disagreed about whether emotional responses occur in the absence of cognitive

processing. How would you characterize the approach of each of the following researchers: Zajonc, LeDoux, Lazarus, Schachter, and Singer?

ANSWER: Zajonc and LeDoux suggested that we experience some emotions without any conscious, cognitive appraisal. Lazarus, Schachter, and Singer emphasized the importance of appraisal and cognitive labeling in our experience of emotion.

Embodied Emotion

Whether you are falling in love or grieving a death, you need little convincing that emotions involve the body. Feeling without a body is like breathing without lungs. Some physical responses are easy to notice. Other emotional responses we experience without awareness.

Emotions and the Autonomic Nervous System

LOQ 12-3 What is the link between emotional arousal and the autonomic nervous system?

In a crisis, the *sympathetic division* of your *autonomic nervous system (ANS)* mobilizes your body for action ([FIGURE 12.3](#)). It directs your adrenal glands to release the stress hormones epinephrine (adrenaline) and norepinephrine (noradrenaline). To provide energy, your liver pours extra sugar into your bloodstream. To help burn the sugar, your respiration increases to supply needed oxygen. Your heart rate and blood pressure increase. Your digestion slows, diverting blood from your internal organs to your muscles. With blood sugar driven into the large muscles, running becomes easier. Your pupils dilate, letting in more light. To cool your stirred-up body, you perspire. If wounded, your blood would clot more quickly.

Autonomic Nervous System Controls Physiological Arousal		
Sympathetic division (arousing)		Parasympathetic division (calming)
Pupils dilate	EYES	Pupils contract
Decreases	SALIVATION	Increases
Perspires	SKIN	Dries
Increases	RESPIRATION	Decreases
Accelerates	HEART	Slows
Inhibits	DIGESTION	Activates
Secrete stress hormones	ADRENAL GLANDS	Decrease secretion of stress hormones
Reduced	IMMUNE SYSTEM FUNCTIONING	Enhanced

FIGURE 12.3 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.3 Emotional arousal

Like a crisis control center, the autonomic nervous system arouses the body in a crisis and calms it when danger passes.

When the crisis passes, the *parasympathetic division* of your ANS gradually calms your body, as stress hormones slowly leave your bloodstream. After your next crisis, think of this: Without any conscious effort, your body's response to danger is wonderfully coordinated and adaptive—preparing you to *fight* or *flee*. So, do the different emotions have distinct arousal fingerprints?

The Physiology of Emotions

LOQ 12-4 Do different emotions activate different physiological and brain-pattern responses?

Imagine conducting an experiment measuring the physiological responses of emotion. In each of four rooms, you have someone watch a movie: In the first, the person views a horror film; in the second, an anger-provoking film; in the third, a sexually arousing film; in the fourth, a boring film. From the control center, you monitor each person's perspiration, pupil size, breathing, and heart rate. Could you tell who is frightened? Who is angry? Who is sexually aroused? Who is bored?

With training, you could probably pick out the bored viewer. But discerning physiological differences among fear, anger, and sexual arousal is much more difficult (Barrett, 2006). Different emotions can share common biological signatures.

A single brain region can also serve as the seat of seemingly different emotions. Consider the broad emotional portfolio of the *insula*, a neural

center deep inside the brain. The insula is activated when we experience various negative social emotions, such as lust, pride, and disgust. In brain scans, it becomes active when people bite into some disgusting food, smell disgusting food, think about biting into a disgusting cockroach, or feel moral disgust over a sleazy business exploiting a saintly widow (Sapolsky, 2010). Similar multitasking regions are found in other brain areas.

“Fear lends wings to his feet.”

Virgil, *Aeneid*, 19 B.C.E.

To review and then check your understanding of the ANS in action, engage online with **Concept Practice: The Autonomic Nervous System**.

Gary Dobner/Alamy

Scary thrills

Elated excitement and panicky fear involve similar physiological arousal. That allows us to flip rapidly between the two emotions.

Yet our varying emotions *feel* different to us, and they often *look* different to others. We may appear “paralyzed with fear” or “ready to explode.” Fear and joy prompt a similar increased heart rate, but they stimulate different facial muscles. During fear, your brow muscles tense. During joy, muscles in your cheeks and under your eyes pull into a smile (Witvliet & Vrana, 1995).

Some of our emotions also differ in their brain circuits (Panksepp, 2007). Observers watching fearful faces showed more amygdala activity than did other observers who watched angry faces (Whalen et al., 2001). Brain scans and EEG recordings show that emotions also activate different areas of the

brain's cortex. When you experience negative emotions such as disgust, your right prefrontal cortex tends to be more active than the left. Depression-prone people, and those with generally negative personalities, have also shown more right frontal lobe activity (Harmon-Jones et al., 2002).

Positive moods tend to trigger more left frontal lobe activity. People with positive personalities—exuberant infants and alert, energized, and persistently goal-directed adults—have also shown more activity in the left frontal lobe than in the right (Davidson, 2000; Urry et al., 2004). Indeed, the more a person's baseline frontal lobe activity tilts left—or is made to tilt left by perceptual activity—the more upbeat the person typically is (Drake & Myers, 2006).

To sum up, we can't easily see differences in emotions from tracking heart rate, breathing, and perspiration. But facial expressions and brain activity can vary with the emotion. So, do we, like Pinocchio, give off telltale signs when we lie? For more on that question, see [Thinking Critically About: Lie Detection](#).

LOQ 12-5 How effective are polygraphs in using body states to detect lies?

Thinking Critically About: Lie Detection

Polygraphs measure emotion-linked changes in breathing, heart rate, and perspiration. Can we use these results to detect lies?

In the last 20 years, have you ever taken something that didn't belong to you? **No!**

Did you ever steal anything from your previous employer? **Uh, no.**

Many people tell a little white lie in response to this *control question*, prompting elevated arousal readings that give the examiner a baseline for comparing responses to other questions.

This person shows greater arousal in response to the *critical question* than she did to the control question, so the examiner may infer she is lying.

But is it true that only a thief becomes nervous when denying a theft?

1. We have similar bodily arousal in response to anxiety, irritation, and guilt. So, is she really guilty, or just anxious?
2. Many innocent people do get tense and nervous when accused of a bad act. (Many rape victims, for example, have "failed" these tests because they had strong emotional reactions while telling the truth about the rapist.¹)

About one-third of the time, polygraph test results are **just wrong**.²

Innocent people

Guilty people

Legend: Yellow = Judged innocent by polygraph, Grey = Judged guilty by polygraph

If these polygraph experts had been the judges, more than one-third of the innocent would have been declared guilty, and nearly one-fourth of the guilty would have gone free.

The CIA and other U.S. agencies have spent millions of dollars testing tens of thousands of employees. Yet the U.S. National Academy of Sciences (2002) has reported that "no spy has ever been caught [by] using the polygraph."

The Concealed Information Test is more effective. Innocent people are seldom wrongly judged to be lying.

Questions focus on specific crime-scene details known only to the police and the guilty person.³ (If a camera and computer had been stolen, for example, only a guilty person should react strongly to the brand names of the stolen items.)

1. Lykken, 1991. 2. Kleinmuntz & Szucko, 1984. 3. Ben-Shakhar & Elaad, 2003; Verschuere & Meijer, 2014; Vrij & Fisher, 2016.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

polygraph a machine used in attempts to detect lies that measures several of the physiological responses (such as perspiration, heart rate, and breathing changes) accompanying emotion.

“No one ever told me that grief felt so much like fear. I am not afraid, but the sensation is like being afraid. The same fluttering in the stomach, the same restlessness, the yawning. I keep on swallowing.”

C. S. Lewis, *A Grief Observed*, 1961

RETRIEVAL PRACTICE

RP-4 How do the two divisions of the autonomic nervous system affect our emotional responses?

ANSWER: The *sympathetic division* of the ANS arouses us for more intense experiences of emotion, pumping out the stress hormones epinephrine and norepinephrine to prepare our body for fight or flight. The *parasympathetic division* of the ANS takes over when a crisis passes, restoring our body to a calm physiological and emotional state.

To see how skilled you are at lie detection, visit **PsychSim 6: Catching Liars**.

REVIEW Introduction to Emotion

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

The _____ - _____ theory of emotion maintains that a physiological response happens BEFORE we know what we are feeling.

Assume that after spending an hour on a treadmill, you receive a letter saying that your scholarship application has been approved. The two-factor theory of emotion would predict that your physical arousal will

- a. weaken your happiness.
- b. intensify your happiness.

- c. transform your happiness into relief.
- d. have no particular effect on your happiness.

Zajonc and LeDoux maintain that some emotional reactions occur before we have had the chance to consciously label or interpret them. Lazarus noted the importance of how we appraise events. These psychologists differ in the emphasis they place on _____ in emotional responses.

- a. physical arousal
- b. the hormone epinephrine
- c. cognitive processing
- d. learning

What does a polygraph measure, and why are its results questionable?

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Expressing Emotion

Expressive behavior implies emotion. Dolphins, with smiles seemingly plastered on their faces, appear happy. To decipher people's emotions we read their bodies, listen to their voice tones, and study their faces. Does nonverbal language vary with culture—or is it universal? And do our expressions influence our experienced emotions?

“Your face, my thane, is a book where men may read strange matters.”

Lady Macbeth to her husband, in William Shakespeare's *Macbeth*

Detecting Emotion in Others

LOQ 12-6 How do we communicate nonverbally?

To Westerners, a firm handshake conveys an outgoing, expressive personality (Chaplin et al., 2000). A glance can communicate intimacy, while darting eyes may signal anxiety (Kleinke, 1986; Perkins et al., 2012). When two people are passionately in love, they typically spend time—quite a bit of time—gazing into each other's eyes (Bolmont et al., 2014; Rubin, 1970). Would such gazes stir these feelings between strangers? To find out, researchers have asked unacquainted male-female (and presumed heterosexual) pairs to gaze intently for 2 minutes either at each other's hands or into each other's eyes. After separating, the eye gazers reported feeling a tingle of attraction and affection (Kellerman et al., 1989).

Ruby/Alamy

A silent language of emotion

Hindu classic dance uses the face and body to effectively convey 10 different emotions (Hejmadi et al., 2000).

Our brain is an amazing detector of subtle expressions, helping most of us read nonverbal cues well. We are adept at detecting a hint of a smile (Maher et al., 2014). Shown 10 seconds of video from the end of a speed-dating interaction, people can often tell whether one person is attracted to another (Place et al., 2009). Signs of status are also easy to spot. When shown someone with arms raised, chest expanded, and a slight smile, people—from Canadian undergraduates to Fijian villagers—perceive that person as experiencing pride and having high status (Tracy et al., 2013). Even glimpsing a face for one-tenth of a second has enabled viewers to judge people’s attractiveness or trustworthiness, or to rate politicians’ competence and predict their voter support (Willis & Todorov, 2006). “First impressions . . . occur with astonishing speed,” note Christopher Olivola and Alexander Todorov (2010).

We also excel at detecting nonverbal threats. We readily sense subliminally presented negative words, such as *snake* or *bomb* (Dijksterhuis & Aarts, 2003). A single, angry face will “pop out” of a crowd (Hansen & Hansen, 1988; Pinkham et al., 2010). Experience can sensitize us to particular emotions, as shown by experiments using a series of faces (like those in [FIGURE 12.4](#)) that morph from anger to fear (or sadness). Viewing such faces, physically abused children are much quicker than other children to spot the signals of anger. Shown a face that is 50 percent fear and 50 percent anger, they are more likely to perceive anger than fear. Their perceptions

become sensitively attuned to glimmers of danger that nonabused children miss.

FIGURE 12.4 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Paul Ekman, Ph.D./Paul Ekman Group, LLC.

FIGURE 12.4 Experience influences how we perceive emotions

Viewing the morphed middle face, evenly mixing anger with fear, physically abused children were more likely than nonabused children to perceive the face as angry (Pollak & Kistler, 2002; Pollak & Tolley-Schell, 2003).

Hard-to-control facial muscles can reveal emotions you may be trying to conceal. Lifting just the inner part of your eyebrows, which few people do consciously, reveals distress or worry. Eyebrows raised and pulled together signal fear. Raised cheeks and activated muscles under the eyes suggest a natural smile. A feigned smile, such as one we make for a photographer, is often frozen in place for several seconds, then suddenly switched off (FIGURE 12.5). Genuine happy smiles tend to be briefer and to fade less abruptly (Bugental, 1986). If you have the urge to hide your happiness, remember that genuine smiles cause others to perceive us as trustworthy, authentic, and attractive (Gunnery & Ruben, 2016). Let your smile shine.

FIGURE 12.5 Which of researcher Paul Ekman's smiles is feigned, which natural?

The smile on the right engages the facial muscles of a natural smile.

Despite our brain's emotion-detecting skill, we find it difficult to discern deceit. The behavioral differences between liars and truth tellers are too minute for most people to detect (Hartwig & Bond, 2011). In one digest of 206 studies, people were just 54 percent accurate in discerning truth from lies—barely better than a coin toss (Bond & DePaulo, 2006). Moreover, virtually no one—save perhaps police professionals in high-stakes situations—beats chance by much (Bond & DePaulo, 2008; O'Sullivan et al., 2009).

Some of us more than others are sensitive to the physical cues of various emotions. In one study, people named the emotion displayed in brief film clips. The clips showed portions of a person's emotionally expressive face or body, sometimes accompanied by a garbled voice (Rosenthal et al., 1979). For example, after a 2-second scene revealing only the face of an upset woman, the researchers would ask whether the woman was criticizing someone for being late or was talking about her divorce. Given such “thin slices,” some people were much better emotion detectors than others. Introverts tend to excel at reading others' emotions, while extraverts are generally easier to read (Ambady et al., 1995).

Gestures, facial expressions, and voice tones, which are absent in written communication, convey important information. The difference was clear when study participants in one group heard 30-second recordings of people describing their marital separations. Participants in the other group read a script of the recording. Those who *heard* the recording were better able to predict the people's current and future adjustment (Mason et al., 2010). Just hearing a stranger say “hello” is enough to give listeners some clue to the speaker's personality. Researcher Phil McAleer and his colleagues (2014) call this “the Jerry Maguire effect,” after the movie in which Renée Zellweger says to Tom Cruise, “You had me at hello.”

The absence of expressive emotion can make for ambiguous emotion in electronic communications. To partly remedy that, we often embed visual cues to emotion 😊 in our messages. Without the vocal nuances that signal whether our statement is serious, kidding, or sarcastic, we are in danger of what developmental psychologist Jean Piaget called *egocentrism*, by failing to perceive how others interpret our “just kidding” message (Kruger et al., 2005).

Gender, Emotion, and Nonverbal Behavior

LOQ 12-7 How do the genders differ in their ability to communicate nonverbally?

Is women's intuition superior to men's, as so many people believe (Gigerenzer et al., 2014)? Do women have greater sensitivity than men to nonverbal cues? After analyzing 125 studies, Judith Hall (1984, 1987) concluded that, when given thin slices of behavior, women generally do surpass men at reading people's emotional cues. The female advantage emerges early in development. Female infants, children, and adolescents have outperformed males in many studies (McClure, 2000). Women's nonverbal sensitivity helps explain their greater emotional literacy. When invited to describe how they would feel in certain situations, men tend to describe simpler emotional reactions (Barrett et al., 2000). You might like to try this yourself: Ask some people how they might feel when saying good-bye to friends after graduation. Research suggests men are more likely to say, simply, "I'll feel bad," and women to express more complex emotions: "It will be bittersweet; I'll feel both happy and sad."

Women's skill at decoding others' emotions may also contribute to their greater emotional responsiveness and expressiveness (Fischer & LaFrance, 2015; Vigil, 2009). In studies of 23,000 people from 26 cultures, women more than men reported themselves open to feelings (Costa et al., 2001). Girls also express stronger emotions than boys do, hence the extremely strong perception that emotionality is "more true of women"—a perception expressed by nearly 100 percent of 18- to 29-year-old Americans (Chaplin & Aldao, 2013; Newport, 2001).

One exception: Quickly—imagine an angry face. What gender is the person? If you're like 3 in 4 Arizona State University students, you imagined a male (Becker et al., 2007). And when a gender-neutral face was made to look angry, most people perceived it as male. If the face was smiling, they were more likely to perceive it as female ([FIGURE 12.6](#)). Anger strikes most people as a more masculine emotion.

FIGURE 12.6 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Vaughn Becker/© APA

FIGURE 12.6 Male or female?

Researchers manipulated a gender-neutral face. People were more likely to see it as male when it wore an angry expression and female when it wore a smile (Becker et al., 2007).

The perception of women's emotionality also feeds—and is fed by—people's attributing women's emotionality to their disposition and men's to their circumstances: “She’s emotional. He’s having a bad day” (Barrett & Bliss-Moreau, 2009). Many factors influence our attributions, including cultural norms (Mason & Morris, 2010). Nevertheless, there are some gender differences in descriptions of emotional experiences. When surveyed, women are also far more likely than men to describe themselves as empathic. If you have *empathy*, you identify with others and appraise a situation as they do, rejoicing with those who rejoice and weeping with those who weep (Wondra & Ellsworth, 2015). Fiction readers, who immerse themselves in the lives of their favorite characters, report higher empathy levels (Mar et al., 2009). This may help explain why, compared with men, women read more fiction (Tepper, 2000). But physiological measures, such as heart rate while seeing another's distress, reveal a much smaller gender gap (Eisenberg & Lennon, 1983; Rueckert et al., 2010).

SIPRESS

"Now, that wasn't so hard, was it?"

David Sipress

Females are also more likely to *express* empathy—to display more emotion when observing someone else's emotions. As [FIGURE 12.7](#) shows, this gender difference was clear when male and female students watched film clips that were sad (children with a dying parent), happy (slapstick comedy), or frightening (a man nearly falling off the ledge of a tall building) (Kring & Gordon, 1998). Women also tend to experience emotional events, such as viewing pictures of mutilation, more deeply and with more brain activation in areas sensitive to emotion. And they better remember the scenes three weeks later (Canli et al., 2002).

FIGURE 12.7 Gender and expressiveness

Male and female film viewers did not differ dramatically in self-reported emotions or physiological responses. But the women's faces *showed* much more emotion.

RETRIEVAL PRACTICE

RP-5 _____ (Women/Men) report experiencing emotions more deeply, and they tend to be more adept at reading nonverbal behavior.

ANSWER: Women

Culture and Emotional Expression

LOQ 12-8 How are gestures and facial expressions understood within and across cultures?

The meaning of *gestures* varies with the culture. U.S. President Richard

Nixon learned this after making the North American “A-OK” sign before a welcoming crowd of Brazilians, not realizing it was a crude insult in that country. The importance of cultural definitions of gestures was again demonstrated in 1968, when North Korea publicized photos of supposedly happy officers from a captured U.S. Navy spy ship. In the photo, three men had raised their middle finger, telling their captors it was a “Hawaiian good luck sign” (Fleming & Scott, 1991).

Do *facial expressions* also have different meanings in different cultures? To find out, two investigative teams showed photographs of various facial expressions to people in different parts of the world and asked them to guess the emotion (Ekman, 1994, 2016; Izard, 1977, 1994). You can try this matching task yourself by pairing the six emotions with the six faces in [FIGURE 12.8](#).

FIGURE 12.8 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Ekman & Matsumoto, Japanese and Caucasian Facial Expressions of Emotions

FIGURE 12.8 Culture-specific or culturally universal expressions?

As people of differing cultures, do our faces speak differing languages? Which face expresses disgust? Anger? Fear? Happiness? Sadness? Surprise? (From Matsumoto & Ekman, 1989)¹

Regardless of your cultural background, you probably did pretty well. A smile’s a smile the world around. Ditto for sadness, and to a lesser extent the other basic expressions (Crivelli et al., 2016a; Jack et al., 2012). There is no culture where people frown when they are happy.

Facial expressions do convey some nonverbal accents that provide clues to one’s culture (Crivelli et al., 2016b; Marsh et al., 2003). Thus, data from 182

studies have shown slightly enhanced accuracy when people judged emotions from their own culture (Elfenbein & Ambady, 2002; Laukka et al., 2016). Still, the telltale signs of emotion generally cross cultures. The world over, children cry when distressed, shake their heads when defiant, and smile when they are happy. So, too, with blind children who have never seen a face (Eibl-Eibesfeldt, 1971). People blind from birth spontaneously exhibit the common facial expressions associated with such emotions as joy, sadness, fear, and anger (Galati et al., 1997).

Do these shared emotional categories reflect shared *cultural* experiences, such as movies and TV broadcasts seen around the world? Apparently not. Paul Ekman and Wallace Friesen (1971) asked isolated people in New Guinea to respond to such statements as, “Pretend your child has died.” When North American college and university students viewed the recorded responses, they easily read the New Guineans’ facial reactions.

So we can say that facial muscles speak a universal language. This discovery would not have surprised Charles Darwin (1809–1882), who argued that in prehistoric times, before our ancestors communicated in words, they communicated threats, greetings, and submission with facial expressions. Their shared expressions helped them survive (Hess & Thibault, 2009). In confrontations, for example, a human sneer retains elements of an animal baring its teeth in a snarl. Emotional expressions may enhance our survival in other ways, too. Surprise raises the eyebrows and widens the eyes, enabling us to take in more information. Disgust wrinkles the nose, closing it from foul odors.

Smiles are social as well as emotional events. Euphoric Olympic gold-medal winners typically don’t smile when they are awaiting their award ceremony. But they wear broad grins when interacting with officials and when facing the crowd and cameras (Fernández-Dols & Ruiz-Belda, 1995). Thus, a glimpse at competitors’ spontaneous expressions following Olympic and national judo competitions gives a very good clue to who won, no matter their country (Crivelli et al., 2015; Matsumoto & Willingham, 2006, 2009). Even natively blind athletes, who have never observed smiles, display social smiles in such situations (Matsumoto et al., 2009).

“For news of the heart, ask the face.”

Guinean proverb

Scott Olson/Getty Images

Universal emotions

No matter where on Earth you live, you have no trouble recognizing the joy experienced by Chicago Cubs fans over their 2016 World Series victory following a 108-year wait.

For a 4-minute demonstration of our universal facial language, see the **Video: Emotions and Facial Expression**.

While weightless, astronauts' internal bodily fluids move toward their upper body and their faces become puffy. This makes nonverbal communication more difficult, especially among multinational crews (Gelman, 1989).

Although we share a universal facial language for some emotions, it has been adaptive for us to interpret faces in particular contexts ([FIGURE 12.9](#)). People judge an angry face set in a frightening situation as afraid. They judge a fearful face set in a painful situation as pained (Carroll & Russell, 1996). Movie directors harness this phenomenon by creating scenes and soundtracks that amplify our perceptions of particular emotions.

FIGURE 12.9 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
 Paul Ekman, Ph.D./Paul Ekman Group, LLC; R. R. Provine. Emotional tears and NGF:
 A biographical appreciation and research beginning. *Archives Italiennes de Biologie*, 149, 271–276.

FIGURE 12.9 We read faces in context

Whether we perceive the man in the top row as disgusted or angry depends on which body his face appears on (Aviezer et al., 2008). In the second row, tears on a woman's face make her expression seem sadder (Provine et al., 2009).

Cultures may share a facial language, but they differ in how *much* emotion they express. Those that encourage individuality, as in Western Europe, Australia, New Zealand, and North America, display visible emotions (van Hemert et al., 2007). Those that encourage people to adjust to others, as in Japan and China, often have less visible emotional displays (Matsumoto et al., 2009; Tsai et al., 2007). In Japan, people infer emotion more from the surrounding context. Moreover, the mouth, often so expressive in North Americans, conveys less emotion than do the telltale eyes (Masuda et al., 2008; Yuki et al., 2007). Compared with their counterparts in China, where calmness is emphasized, European-American leaders express excited smiles six times more frequently in their official photos ([FIGURE 12.10](#)) (Tsai et al., 2006, 2016). If we're happy and we know it, our culture will teach us how to show it.

FIGURE 12.10 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers
Peter Probst/Alamy; AP

FIGURE 12.10 Culture and smiling

Former U.S. Vice President Joe Biden's broad smile and Chinese President Xi Jinping's more reserved one illustrate a cultural difference in facial expressiveness.

Cultural differences also exist *within* nations. The Irish and their Irish-American descendants have tended to be more expressive than the Scandinavians and their Scandinavian-American descendants (Tsai & Chentsova-Dutton, 2003). And that reminds us of a familiar lesson: Like most psychological events, emotion is best understood not only as a biological and cognitive phenomenon, but also as a social-cultural phenomenon.

RETRIEVAL PRACTICE

RP-6 Are people more likely to differ culturally in their interpretations of facial expressions, or of gestures?

ANSWER: gestures

The Effects of Facial Expressions

LOQ 12-9 How do our facial expressions influence our feelings?

As William James (1890) struggled with feelings of depression and grief, he came to believe that we can control emotions by going “through the outward movements” of any emotion we want to experience. “To feel cheerful,” he

advised, “sit up cheerfully, look around cheerfully, and act as if cheerfulness were already there.”

Studies of emotional effects of facial expressions support what James predicted. Expressions not only communicate emotion, they also amplify and regulate it. In *The Expression of the Emotions in Man and Animals*, Charles Darwin (1872) contended that “the free expression by outward signs of an emotion intensifies it. . . . He who gives way to violent gestures will increase his rage.”

Was Darwin right? You can test his hypothesis: Fake a big grin. Now scowl. Can you feel the “smile therapy” difference? Participants in dozens of experiments have felt a difference. Researchers subtly induced students to make a frowning expression by asking them to “contract these muscles” and “pull your brows together” (supposedly to help the researchers attach facial electrodes) (Laird, 1974, 1984; Laird & Lacasse, 2014). The results? The students reported feeling a little angry, as do people who are naturally frowning (by squinting) when facing the Sun (Marzoli et al., 2013). So, too, for other basic emotions. For example, people reported feeling more fear than anger, disgust, or sadness when made to construct a fearful expression: “Raise your eyebrows. And open your eyes wide. Move your whole head back, so that your chin is tucked in a little bit, and let your mouth relax and hang open a little” (Duclos et al., 1989).

This [facial feedback effect](#) has been found many times, in many places, for many basic emotions ([FIGURE 12.11](#)). Just activating one of the smiling muscles by holding a pen in the teeth (rather than gently between the lips, which produces a neutral expression) makes stressful situations less upsetting (Kraft & Pressman, 2012). A hearty smile—made not just with the mouth but with raised cheeks that crinkle the eyes—enhances positive feelings even more when you are reacting to something pleasant or funny (Soussignan, 2001). When happy we smile, and when smiling we become happier. When smiling, you will even more quickly understand sentences that describe pleasant events (Havas et al., 2007). Although some researchers question the reliability of the facial feedback effect (Wagenmakers et al., 2016), many others have replicated it (Strack, 2016).

facial feedback effect the tendency of facial muscle states to trigger corresponding feelings such as fear, anger, or happiness.

FIGURE 12.11 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.11 How to make people smile without telling them to smile

Do as Kazuo Mori and Hideko Mori (2009) did with students in Japan: Attach rubber bands to the sides of the face with adhesive bandages, and then run them either over the head or under the chin.

“Whenever I feel afraid
I hold my head erect
And whistle a happy tune.”

Richard Rodgers and Oscar Hammerstein, *The King and I*, 1958

RETRIEVAL PRACTICE

RP-7 (1) Based on the *facial feedback effect*, how might students report feeling when the rubber bands raise their cheeks as though in a smile? (2) How might students report feeling when the rubber bands pull their cheeks downward?

ANSWER: (1) Most students report feeling more happy than sad when their cheeks are raised upward. (2) Most students report feeling more sad than happy when their cheeks are pulled downward.

So, your face is more than a billboard that displays your feelings; it also feeds your feelings. Scowl and the whole world scowls back. No wonder

some depressed patients reportedly felt better after Botox injections paralyzed their frowning muscles (Parsaik et al., 2016). Botox paralysis of the frowning muscles slows people's reading of sadness- or anger-related sentences, and it slows activity in emotion-related brain circuits (Havas et al., 2010; Hennenlotter et al., 2008).

A request from your authors: Smile often as you read this book.

Other researchers have observed a similar [behavior feedback effect](#) (Carney et al., 2015; Flack, 2006). You can duplicate the participants' experience: Walk for a few minutes with short, shuffling steps, keeping your eyes downcast. Now walk around taking long strides, with your arms swinging and your eyes looking straight ahead. Can you feel your mood shift? Going through the motions awakens the emotions.

behavior feedback effect the tendency of behavior to influence our own and others' thoughts, feelings, and actions.

You can use your understanding of feedback effects to become more empathic: Let your own face mimic another person's expression. Acting as another acts helps us feel what another feels (Vaughn & Lanzetta, 1981). Losing this ability to mimic others can leave us struggling to make emotional connections, as one social worker with Moebius syndrome, a rare facial paralysis disorder, discovered while working with Hurricane Katrina refugees: When people made a sad expression, "I wasn't able to return it. I tried to do so with words and tone of voice, but it was no use. Stripped of the facial expression, the emotion just dies there, unshared" (Carey, 2010).

Our natural mimicry of others' emotions helps explain why emotions are contagious (Dimberg et al., 2000; Neumann & Strack, 2000; Peters & Kashima, 2015). Positive, upbeat Facebook posts create a ripple effect, leading Facebook friends to also express more positive emotions (Kramer, 2012).

REVIEW Expressing Emotion

LEARNING OBJECTIVES

Test yourself by taking a moment to answer each of these Learning Objective Questions (repeated here from within this section). Then check your answer—a click away in the e-book, and in [Appendix C](#) of the printed text. Research suggests that trying to answer these questions on your own will improve your long-term retention (McDaniel et al., 2009, 2015).

Experiencing Emotion

LOQ 12-10 What are some of the basic emotions?

How many distinct emotions are there? When surveyed, most emotion scientists agreed that anger, fear, disgust, sadness, and happiness are basic human emotions (Ekman, 2016). Carroll Izard (1977) isolated 10 basic emotions (joy, interest-excitement, surprise, sadness, anger, disgust, contempt, fear, shame, and guilt), most present in infancy ([FIGURE 12.12](#)). Others believe that pride and love are also basic emotions (Shaver et al., 1996; Tracy & Robins, 2004). But Izard has argued that other emotions are combinations of these 10, with love, for example, being a mixture of joy and interest-excitement.

FIGURE 12.12 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
ataphoto/Getty Images; Patrick Donehue/Science Source; Emma Kim/Getty Images; lina aidukaite/Getty Images;
Samuel Borges Photography/Shutterstock; Tao Peng/Getty Images; Vladimir Godnik/Getty Images

FIGURE 12.12 Some naturally occurring infant emotions

To identify the emotions generally present in infancy, Carroll Izard analyzed the facial expressions of infants.

- (a) Joy (mouth forming smile, cheeks lifted, twinkle in eye)
- (b) Anger (brows drawn together and downward, eyes fixed, mouth squarish)
- (c) Interest (brows raised or knitted, mouth softly rounded, lips may be pursed)
- (d) Disgust (nose wrinkled, upper lip raised, tongue pushed outward)
- (e) Surprise (brows raised, eyes widened, mouth rounded in oval shape)

- (f) Sadness (brows' inner corners raised, mouth corners drawn down)
- (g) Fear (brows level, drawn in and up, eyelids lifted, mouth corners retracted)

Let's take a closer look at anger and happiness. What functions do they serve? What influences our experience of each?

Anger

LOQ 12-11 What are the causes and consequences of anger?

Anger, the sages have said, is “a short madness” (Horace, 65–8 B.C.E.) that “carries the mind away” (Virgil, 70–19 B.C.E.) and can be “many times more hurtful than the injury that caused it” (Thomas Fuller, 1654–1734). But they have also said that “noble anger” (William Shakespeare, 1564–1616) “makes any coward brave” (Cato, 234–149 B.C.E.) and “brings back . . . strength” (Virgil).

When we face a threat or challenge, fear triggers flight but anger triggers fight—each at times an adaptive behavior. What makes us angry? Sometimes anger is a response to someone's perceived misdeeds, especially when the person's act seems willful, unjustified, and avoidable (Averill, 1983). But small hassles and blameless annoyances—foul odors, high temperatures, a traffic jam, aches and pains—also have the power to make us angry (Berkowitz, 1990).

Anger can harm us: Chronic hostility is linked to heart disease. Anger boosts our heart rate, causes our skin to drip with sweat, and raises our testosterone levels (Herrero et al., 2010; Kubo et al., 2012; Peterson & Harmon-Jones, 2012). How, then, can we manage our anger? In a Gallup teen survey, boys more than girls reported walking away from the situation or working it off with exercise; girls more often reported talking with a friend, listening to music, or writing (Ray, 2005). Popular books and articles sometimes advise that releasing angry feelings can be better than internalizing them. When irritated, should we lash out at the offender? Should we rage at our dead parents, imaginatively curse the boss, or confront our childhood abuser?

MIKE HUTCHINGS/REUTERS/Newscom

Blowing off steam

Fans seem to experience a *temporary release* while cheering at World Cup soccer matches, such as this one in South Africa. My [DM's] daughter, a resident, noted, "Every time I got angry at Uruguay, blowing that vuvuzela and joining the chorus of dissent released something in me."

Individualist cultures do encourage people to vent their rage. Such advice is seldom heard in cultures where people's identity is centered more on the group. People who keenly sense their *interdependence* see anger as a threat to group harmony (Markus & Kitayama, 1991). In Tahiti, for instance, people learn to be considerate and gentle. In Japan, from infancy on, angry expressions are less common than in Western cultures, where in recent politics and on social media anger seems all the rage.

The Western vent-your-anger advice presumes that aggressive action or fantasy enables emotional release, or [catharsis](#). Experimenters report that *sometimes* when people retaliate against a provoker, they may calm down if they direct their counterattack toward the provoker, their retaliation seems justifiable, and their target is not intimidating (Geen & Quanty, 1977; Hokanson & Edelman, 1966; Verona & Sullivan, 2008). In short, expressing

anger can be *temporarily* calming if it does not leave us feeling guilty or anxious.

catharsis in psychology, the idea that “releasing” aggressive energy (through action or fantasy) relieves aggressive urges.

Isabella Bannerman,
Distributed by King Features Syndicate

The catharsis idea: Is it true?

Despite this temporary afterglow, catharsis usually fails to cleanse our rage. More often, expressing anger breeds more anger. For one thing, it may provoke further retaliation, causing a minor conflict to escalate into a major confrontation. For another, expressing anger can magnify anger. As *behavior feedback* research demonstrates, *acting* angry can make us *feel* angrier (Flack, 2006; Snodgrass et al., 1986). Anger’s backfire potential appeared in a study of people who were asked to wallop a punching bag while ruminating about the person who had recently angered them (Bushman, 2002). Had the opportunity to “drain off” their anger reduced it? Quite the contrary. Later, when given a chance for revenge, those who vented their anger became even more aggressive.

When anger fuels physically or verbally aggressive acts we later regret, it becomes maladaptive. Anger primes prejudice. After the 9/11 terrorist

attacks, Americans who responded with anger more than fear displayed intolerance for immigrants and Muslims (DeSteno et al., 2004; Skitka et al., 2004). Angry outbursts that temporarily calm us may also become reinforcing and therefore habit forming. If stressed managers find they can temporarily drain off some of their tension by berating an employee, then the next time they feel irritated and tense they may be more likely to explode again.

What are some better ways to manage your anger? Experts offer three suggestions:

- *Wait.* Doing so will reduce your physiological arousal. “What goes up must come down,” noted Carol Tavris (1982). “Any emotional arousal will simmer down if you just wait long enough.”
- *Find a healthy distraction or support.* Calm yourself by exercising, playing an instrument, or talking things through with a friend. Brain scans show that ruminating inwardly about why you are angry serves only to increase amygdala bloodflow (Fabiansson et al., 2012).
- *Distance yourself.* Try to move away from the situation mentally, as if you are watching it unfold from a distance or the future. Self-distancing reduces rumination, anger, and aggression (Kross & Ayduk, 2011; Mischkowski et al., 2012; White et al., 2015).

“Venting to reduce anger is like using gasoline to put out a fire.”

Researcher Brad Bushman, 2002

“Anger will never disappear so long as thoughts of resentment are cherished in the mind.”

The Buddha, 500 B.C.E.

Anger is not always wrong. Used wisely, it communicates strength and competence (Tiedens, 2001). Anger also motivates people to act courageously and achieve goals (Aarts & Custers, 2012; Halmburger et al., 2015). Controlled expressions of anger are more adaptive than either hostile outbursts or pent-up angry feelings. When James Averill (1983) asked people

to recall or keep careful records of their experiences with anger, they often recalled reacting assertively rather than hurtfully. Their anger frequently led them to talk things over with the offender, thereby lessening the aggravation. Civility means not only keeping silent about trivial irritations but also communicating important ones clearly and assertively. A nonaccusing statement of feeling—perhaps letting one’s housemate know that “I get irritated when I have to clean up your dirty dishes”—can help resolve conflicts. Anger that expresses a grievance in ways that promote reconciliation rather than retaliation can benefit a relationship.

What if someone’s behavior really hurts you, and you cannot resolve the conflict? Research commends the age-old response of forgiveness. Without letting the offender off the hook or inviting further harm—sometimes we need to distance ourselves from an abusive person—forgiveness may release anger and calm the body. In a study of the neural effects of forgiveness, German students had their brain scanned while someone thwarted their opportunity to earn money (Strang et al., 2014). Next, the students were asked whether or not they forgave the wrongdoer. Forgiveness increased bloodflow to brain regions that help people understand their own emotions and make socially appropriate decisions.

RETRIEVAL PRACTICE

- RP-8 Which one of the following is an effective strategy for reducing angry feelings?
- a. Retaliate verbally or physically.
 - b. Wait or “simmer down.”
 - c. Express anger in action or fantasy.
 - d. Review the grievance silently.

ANSWER: RP-8 b.

Happiness

LOQ 12-12 What is the *feel-good, do-good phenomenon*, and what is the focus of positive psychology research?

People aspire to, and wish one another, health and happiness. And for good reason. Our state of happiness or unhappiness colors everything. Happy people perceive the world as safer. Their eyes are drawn toward emotionally positive information (Raila et al., 2015). They are more confident and decisive, and they cooperate more easily. They rate job applicants more favorably, savor their positive past experiences without dwelling on the negative, and are more socially connected. They live healthier and more energized and satisfied lives (Boehm et al., 2015a; De Neve et al., 2013; Stellar et al., 2015). And they are more generous (Boenigk & Mayr, 2016). The simple conclusion: *Moods matter*. When you are gloomy, life as a whole seems depressing and meaningless—and you think more skeptically and attend more critically to your surroundings. Let your mood brighten and your thinking broadens, becoming more playful and creative (Baas et al., 2008; Forgas, 2008; Fredrickson, 2013).

College and university students' happiness helps predict their future life course. One study showed that the happiest 20-year-olds were later more likely to marry and less likely to divorce (Stutzer & Frey, 2006). In another study, which surveyed thousands of U.S. college students in 1976 and restudied them at age 37, happy students had gone on to earn significantly more money than their less-happy-than-average peers (Diener et al., 2002). When we are happy, our relationships, self-image, and hopes for the future also seem more promising.

Moreover—and this is one of psychology's most consistent findings—happiness doesn't just feel good, it *does* good. In study after study, a mood-boosting experience such as recalling a happy event has made people more likely to give money, pick up someone's dropped papers, volunteer time, and do other good deeds. Psychologists call it the [feel-good, do-good phenomenon](#) (Salovey, 1990).

feel-good, do-good phenomenon people's tendency to be helpful when in a good mood.

The reverse is also true: Doing good also promotes good feeling. One survey of more than 200,000 people in 136 countries found that, nearly everywhere, people report feeling happier after spending money on others

rather than on themselves (Aknin et al., 2013; Dunn et al., 2014). Kidney donation leaves donors feeling good (Brethel-Haurwitz & Marsh, 2014). Young children also show more positive emotion when they give, rather than receive, gifts (Aknin et al., 2015). Why does doing good feel so good? One reason is that it strengthens our social relationships (Aknin & Human, 2015; Yamaguchi et al., 2015). Some happiness coaches harness this *do-good, feel-good phenomenon* as they assign people to perform a daily “random act of kindness” and to record the results.

Positive Psychology

William James was writing about the importance of happiness (“the secret motive for all [we] do”) as early as 1902. By the 1960s, the *humanistic psychologists* were interested in advancing human fulfillment. In the twenty-first century, under the leadership of American Psychological Association past-president Martin Seligman, [positive psychology](#) is using scientific methods to study human flourishing. This young subfield includes studies of [subjective well-being](#)—our feelings of happiness (sometimes defined as a high ratio of positive to negative feelings) or our sense of satisfaction with life.

positive psychology the scientific study of human flourishing, with the goals of discovering and promoting strengths and virtues that help individuals and communities to thrive.

subjective well-being self-perceived happiness or satisfaction with life. Used along with measures of objective well-being (for example, physical and economic indicators) to evaluate people’s quality of life.

Taken together, satisfaction with the past, happiness with the present, and optimism about the future define the positive psychology movement’s first pillar: *positive well-being*. Seligman views happiness as a by-product of a pleasant, engaged, and meaningful life.

Courtesy of Martin Seligman

Martin E. P. Seligman

“The main purpose of a positive psychology is to measure, understand, and then build the human strengths and the civic virtues.”

To assess your own well-being and consider ways to improve it, engage online with **Assess Your Strengths: How Satisfied Are You With Your Life, and How Could You Be More Satisfied?**

Positive psychology is about building not just a pleasant life, says Seligman, but also a good life that engages one’s skills, and a meaningful life that points beyond oneself. Thus, the second pillar, *positive character*, focuses on exploring and enhancing creativity, courage, compassion, integrity, self-control, leadership, wisdom, and spirituality.

The third pillar, *positive groups, communities, and cultures*, seeks to foster a positive social ecology. This includes healthy families, communal neighborhoods, effective schools, socially responsible media, and civil dialogue.

“Positive psychology,” Seligman and colleagues have said (2005), “is an umbrella term for the study of positive emotions, positive character traits, and enabling institutions.” Its focus differs from psychology’s traditional interests in understanding and alleviating negative states—abuse and anxiety, depression and disease, prejudice and poverty. Indeed, psychology articles published since 1887 on depression have outnumbered those related to happiness by 15 to 1.

In ages past, times of relative peace and prosperity have enabled cultures

to turn their attention from repairing weakness and damage to promoting what Seligman (2002) has called “the highest qualities of life.” Prosperous fifth-century Athens nurtured philosophy and democracy. Flourishing fifteenth-century Florence nurtured great art. Victorian England, flush with the bounty of the British Empire, nurtured honor, discipline, and duty. In this millennium, Seligman believes, thriving Western cultures have a parallel opportunity to create, as a “humane, scientific monument,” a more positive psychology, concerned not only with weakness and damage but also with strength and virtue. Thanks to his leadership, and to more than \$200 million in funding, the movement has gained strength, with supporters in 77 countries (IPPA, 2017; Seligman, 2016).

The Short Life of Emotional Ups and Downs

LOQ 12-13 How do time, wealth, adaptation, and comparison affect our happiness levels?

Are some days of the week happier than others? In what may be psychology’s biggest-ever data sample, social psychologist Adam Kramer (at my [DM’s] request and in cooperation with Facebook) did a naturalistic observation of emotion words in *billions* of status updates. After eliminating exceptional days, such as holidays, he tracked the frequency of positive and negative emotion words by day of the week. The days with the most positive moods? Friday and Saturday ([FIGURE 12.13](#)). Similar analyses of questionnaire responses and 59 million Twitter messages found Friday to Sunday the week’s happiest days (Golder & Macy, 2011; Helliwell & Wang, 2015; Young & Lim, 2014). For you, too?

FIGURE 12.13 Myers/DeWall, *Psychology*, 12e,
© 2018 Worth Publishers

FIGURE 12.13 Using web science to track happy days

Adam Kramer (2010) tracked positive and negative emotion words in many “billions” (the exact number is proprietary information) of status updates of U.S. Facebook users between September 7, 2007, and November 17, 2010.

See the **Video: Naturalistic Observation** for a helpful tutorial animation about this type of research design.

Over the long run, our emotional ups and downs tend to balance out, even over the course of the day. Positive emotion rises over the early to middle part of most days and then drops off (Kahneman et al., 2004; Watson, 2000). A stressful event—an argument, a sick child, a car problem—can trigger a bad mood. No surprise there. But by the next day, the gloom nearly always lifts (Affleck et al., 1994; Bolger et al., 1989; Stone & Neale, 1984). Our overall judgments of our lives often show lingering effects of good or bad events, but our daily moods typically rebound (Luhmann et al., 2012). If anything, people tend to bounce back from a bad day to a *better-than-usual* good mood the following day.

Worse events—the loss of a spouse or a job—can drag us down for longer periods (Infurna & Luthar, 2016a). But eventually, our bad mood usually ends. A romantic breakup feels devastating, but in time the wound heals. In one study, faculty members up for tenure expected their lives would be

deflated by a negative decision. Actually, 5 to 10 years later, their happiness level was about the same as for those who received tenure (Gilbert et al., 1998).

Grief over the loss of a loved one or anxiety after a severe trauma (such as child abuse, rape, or the terrors of war) can linger. But usually, even tragedy is not permanently depressing. People who become blind or paralyzed may not completely recover their previous well-being, but those with an agreeable personality usually recover near-normal levels of day-to-day happiness (Boyce & Wood, 2011; Hall et al., 1999). So do those who count their blessings and remain optimistic in the wake of a school shooting or terrorist bombing (Birkeland et al., 2016; Vieselmeyer et al., 2017). Even if you lose the use of all four limbs, explained psychologist Daniel Kahneman (2005a), “you will gradually start thinking of other things, and the more time you spend thinking of other things the less miserable you are going to be.” Contrary to what many people believe, even most patients “locked-in” a motionless body do not indicate they want to die (Bruno et al., 2008, 2011; Nizzi et al., 2012; Smith & Delargy, 2005).

The surprising reality: *We overestimate the duration of our emotions and underestimate our resiliency and capacity to adapt.* (As one who inherited hearing loss with a trajectory toward that of my mother, who spent the last 13 years of her life completely deaf, I [DM] take heart from these findings.)

“No happiness lasts for long.”

Seneca, *Agamemnon*, 60 C.E.

“Weeping may tarry for the night, but joy comes with the morning.”

Psalms 30:5

Anna Putt in her wheelchair

Human resilience

Seven weeks after her 1994 wedding, Anna Putt of South Midlands, England, shown here with her husband, Des, suffered a brain-stem stroke that left her “locked-in.” For months after, she recalled, “I was paralyzed from the neck down and was unable to communicate. These were VERY frightening times. But with encouragement from family, friends, faith, and medical staff, I tried to keep positive.” In the ensuing three years, she became able to “talk” (by nodding at letters), to steer an electric wheelchair with her head, and to use a computer (with head movements that guide a cursor). Despite her paralysis, she has reported, “I enjoy going out in the fresh air. My motto is ‘Don’t look back, move forward.’ God would not want me to stop trying and I have no intention of doing so. Life is what you make of it!”

Wealth and Well-Being

Would you be happier if you made more money? In a 2006 Gallup poll, 73 percent of Americans thought they would be. How important is “being very well off financially”? “Very important” or “essential,” say 82 percent of entering U.S. college students (Eagen et al., 2016).

Money does buy happiness, up to a point, especially for people during their midlife working years (Cheung & Lucas, 2015). Moreover, people in rich countries are happier than those in poor countries (Diener & Tay, 2015). Having enough money to buy your way out of hunger, to have a sense of control over your life, and to treat yourself to something special predicts greater happiness (Fischer & Boer, 2011; Ruberton et al., 2016). As Australian data confirm, the power of more money to increase happiness is strongest at low incomes (Cummins, 2006). A \$1000 annual wage increase does a lot more for the average person in Malawi than for the average person

in Switzerland. Raising low incomes will increase happiness more than will raising high incomes.

Once we have enough money for comfort and security, piling up more and more matters less and less. Experiencing luxury diminishes our savoring of life's simpler pleasures (Cooney et al, 2014; Quoidbach et al., 2010). If you ski the Alps once, your neighborhood sledding hill pales. If you ski the Alps every winter, it becomes an ordinary part of life rather than an experience to treasure (Quoidbach et al., 2015).

And consider this: During the last half-century, the average U.S. citizen's buying power almost tripled—enabling larger homes and twice as many cars per person, not to mention iPads and smart phones. Did it also buy more happiness? As [FIGURE 12.14](#) shows, Americans have become no happier. In 1957, some 35 percent said they were “very happy,” as did slightly fewer—33 percent—in 2014. Much the same has been true of Europe, Canada, Australia, and Japan, where increasing real incomes have *not* produced increasing happiness (Australian Unity, 2008; Diener & Biswas-Diener, 2008; Di Tella & MacCulloch, 2010; Zuzanek, 2013). Ditto China, where living standards have risen but life satisfaction has not (Davey & Rato, 2012; Easterlin et al., 2012). These findings lob a bombshell at modern materialism: *Economic growth in affluent countries has provided no apparent boost to people's morale or social well-being.*

FIGURE 12.14 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Happiness data from National Opinion Research Center surveys; income data from Historical Statistics of the United States and Economic Indicators

FIGURE 12.14 Does money buy happiness?

It surely helps us to avoid certain types of pain. Yet, though average buying power has almost tripled since the 1950s, Americans' reported happiness has remained almost unchanged. (Happiness data from National Opinion Research Center surveys; income data from *Historical Statistics of the United States* and *Economic Indicators*.)

Ironically, in every culture, those who strive hardest for wealth have tended to live with lower well-being, especially when they seek money to prove themselves, gain power, or show off rather than support their families (Donnelly et al., 2016; Niemiec et al., 2009; Srivastava et al., 2001). Thinking about money causes people to become less attuned to others—less warm and caring (Vohs, 2015). Those who instead strive for intimacy, personal growth, and community contribution experience a higher quality of life (Kasser et al., 2014).

"But on the positive side, money can't buy happiness—so who cares?"

Harley Schwadron via CartoonStock -
www.cartoonstock.com/cartoonview.asp?catref=hscn1246

"Continued pleasures wear off. . . . Pleasure is always contingent upon change and disappears with continuous satisfaction."

Dutch psychologist Nico Frijda (1988)

Two Psychological Phenomena: Adaptation and

Comparison

Two psychological principles explain why, for those who are not poor, more money buys little more than temporary happiness and why our emotions seem attached to elastic bands that pull us back from highs or lows. In its own way, each principle suggests that happiness is relative.

HAPPINESS IS RELATIVE TO OUR OWN EXPERIENCE The adaptation-level phenomenon describes our tendency to judge various stimuli in comparison with our past experiences. As psychologist Harry Helson (1898–1977) explained, we adjust our *neutral* levels—the points at which sounds seem neither loud nor soft, temperatures neither hot nor cold, events neither pleasant nor unpleasant—based on our experience. We then notice and react to variations up or down from these levels. Thus, after an initial surge of pleasure, improvements become our “new normal,” and we then require something even better to give us a boost of happiness.

adaptation-level phenomenon our tendency to form judgments (of sounds, of lights, of income) relative to a neutral level defined by our prior experience.

So, could we ever create a permanent social paradise? Probably not (Campbell, 1975; Di Tella et al., 2010). People who have experienced a recent windfall—from a lottery, an inheritance, or a surging economy—typically feel elated (Diener & Oishi, 2000; Gardner & Oswald, 2007). So would you, if you woke up tomorrow to your utopia—perhaps a world with no bills, no ills, and perfect exam scores. But eventually, you would adapt to this new normal. Before long, you would again sometimes feel gratified (when events exceed your expectations) and sometimes feel deprived (when they fall below). *The point to remember:* Feelings of satisfaction and dissatisfaction, success and failure are judgments we make based partly on expectations formed by our recent experience (Rutledge et al., 2014). Satisfaction, as Richard Ryan (1999) said, “has a short half-life.” Ditto disappointment, which means that you may bounce back from a setback or from your team’s defeat sooner than you expect.

HAPPINESS IS RELATIVE TO OTHERS’ SUCCESS We are always

comparing ourselves with others. And whether we feel good or bad depends on who those others are (Lyubomirsky, 2001). We are slow-witted or clumsy only when others are smarter or more agile. When we sense that we are worse off than others with whom we compare ourselves, we experience [relative deprivation](#). Satisfaction stems less from our income than from our income rank (Boyce et al., 2010). Better to make \$50,000 when others make \$25,000 than to make \$100,000 when friends, neighbors, and co-workers make \$200,000 (Solnick & Hemenway, 1998, 2009). Likewise, a raise will make you happier if it's greater than the raise received by others around you (Graham, 2011).

relative deprivation the perception that one is worse off relative to those with whom one compares oneself.

When expectations soar above attainments, we feel disappointed. Thus, the middle- and upper-income people in a given country, who can compare themselves with the relatively poor, tend to have greater life satisfaction than their less fortunate compatriots. Nevertheless, once people reach a moderate income level, further increases buy little more happiness. Why? Because as people climb the ladder of success they mostly compare themselves with local peers who are at or above their current level (Gruder, 1977; Suls & Tesch, 1978; Zell & Alicke, 2010). “Beggars do not envy millionaires, though of course they will envy other beggars who are more successful,” noted British philosopher Bertrand Russell (1930/1985, [p. 90](#)). Thus, “Napoleon envied Caesar, Caesar envied Alexander, and Alexander, I daresay, envied Hercules, who never existed. You cannot, therefore, get away from envy by means of success alone, for there will always be in history or legend some person even more successful than you are” (pp. 68–69).

Over the last half-century, inequality in Western countries has increased. For CEOs at America's largest corporations (the Standard & Poor 500), the CEO-to-worker pay ratio—20 to 1 in 1965—rose to 335 to 1 in 2015 (AFL-CIO, 2016; Kiatpongsan & Norton, 2014). The rising economic tide shown in [Figure 12.14](#) has lifted the yachts more than the rowboats. Increasing inequality has accompanied economic growth. Does it matter? Does this explain why economic growth has not been associated with increased

happiness (Oishi & Kesebir, 2015)? Yes. Places with great inequality have higher crime rates, obesity, anxiety, and drug use, and lower life expectancy (Burkhauser et al., 2016; Ratcliff, 2013; Wilkinson & Pickett, 2009). Times and places with greater income inequality also tend to be less happy—a result that people’s social comparisons help explain (Cheung & Lucas, 2016; Helliwell et al., 2013; Roth et al., 2016).

Just as comparing ourselves with those who are better off creates envy, so counting our blessings as we compare ourselves with those worse off boosts our contentment. In one study, university women considered others’ deprivation and suffering (Dermer et al., 1979). They viewed vivid depictions of grim city life in 1900. They imagined and then wrote about various personal tragedies, such as being burned and disfigured. Later, the women expressed greater satisfaction with their own lives. Similarly, when mildly depressed people have read about someone who was even more depressed, they felt somewhat better (Gibbons, 1986). “I cried because I had no shoes,” states a Persian saying, “until I met a man who had no feet.”

For a 6.5-minute examination of historical and modern views of happiness, see the **Video: The Search for Happiness**.

What Predicts Our Happiness Levels?

LOQ 12-14 What predicts happiness, and how can we be happier?

Happy people share many characteristics ([TABLE 12.2](#)). But why are some people normally so joyful and others so somber? Here, as in so many other areas, the answer is found in the interplay between nature and nurture.

TABLE 12.2
Happiness Is . . .

Researchers Have Found That Happy People Tend to	However, Happiness Seems Not Much Related to Other Factors, Such as
Have high self-esteem (in	Age.

individualist countries).	
Be optimistic, outgoing, and agreeable.	Gender (women are more often depressed, but also more often joyful).
Have close, positive, and lasting relationships.	Physical attractiveness.
Have work and leisure that engage their skills.	
Have an active religious faith (especially in more religious cultures).	
Sleep well and exercise.	

Information from De Neve & Cooper (1998); Diener et al. (2003, 2011); Headey et al. (2010); Lucas et al. (2004); Myers (1993, 2000); Myers & Diener (1995, 1996); Steel et al. (2008). Veenhoven (2014, 2015) offers a database of 13,000+ correlates of happiness at WorldDatabaseofHappiness.eur.nl.

“I have a ‘fortune cookie maxim’ that I’m very proud of: Nothing in life is quite as important as you think it is while you are thinking about it. So, nothing will ever make you as happy as you think it will.”

Nobel laureate psychologist Daniel Kahneman, Gallup interview, “What Were They Thinking?” 2005

The effect of comparison with others helps explain why students tend to have a higher academic self-concept if they attend a school where most other students were not exceptionally able (Marsh & Parker, 1984; Rogers & Feller, 2016; Salchegger, 2016). If you were near the top of your graduating class, you might feel inferior or discouraged upon entering a college or university where all students were near the top of

their class.

“Comparison is the thief of joy.”

“Researchers say I’m not happier for being richer, but do you know how much researchers make?”

Pat Byrnes The New Yorker Collection/
The Cartoon Bank

Genes matter. In one analysis of over 55,000 identical and fraternal twins, 36 percent of the differences among people’s happiness ratings was heritable—attributable to genes (Bartels, 2015). Even identical twins raised apart are often similarly happy. Moreover, researchers are now drilling down to identify how specific genes influence our happiness (De Neve et al., 2012; Fredrickson et al., 2013).

But our personal history and our culture matter, too. On the personal level, as we have seen, our emotions tend to balance around a level defined by our experience. On the cultural level, groups vary in the traits they value. Self-esteem and achievement matter more in Western cultures, which value individualism. Social acceptance and harmony matter more in communal cultures such as Japan, which stress family and community (Diener et al., 2003; Fulmer et al., 2010; Uchida & Kitayama, 2009).

Depending on our genes, our outlook, and our recent experiences, our

happiness seems to fluctuate around a “happiness set point,” which disposes some people to be ever upbeat and others more negative. Even so, after following thousands of lives over two decades, researchers have determined that our satisfaction with life can change (Lucas & Donnellan, 2007). Happiness rises and falls, and can be influenced by factors that are under our control (Layous & Lyubomirsky, 2014; Nes et al., 2010). See [TABLE 12.3](#) for research-based suggestions for improving your mood and increasing your satisfaction with life.

TABLE 12.3

Evidence-Based Suggestions for a Happier Life

<ul style="list-style-type: none"> • Take control of your time. Happy people feel in control of their lives: Set goals and divide them into daily aims. We all tend to overestimate how much we will accomplish in any given day, but the good news is that we generally <i>underestimate</i> how much we can accomplish in a year, given just a little daily progress.
<ul style="list-style-type: none"> • Act happy. Research shows that people who are manipulated into a smiling expression feel better. So put on a happy face. Talk as <i>if</i> you feel positive self-esteem, are optimistic, and are outgoing. We can often act our way into a happier state of mind.
<ul style="list-style-type: none"> • Seek work and leisure that engage your skills. Happy people often are in a zone called <i>flow</i>—absorbed in tasks that challenge but don’t overwhelm them. Passive forms of leisure (watching TV) often provide less flow experience than exercising, socializing, or expressing artistic interests.
<ul style="list-style-type: none"> • Buy shared experiences rather than things. Money buys more happiness when spent on experiences, especially on socially shared experiences, that you look forward to, enjoy, remember, and talk about (Caprariello & Reis, 2013; Carter & Gilovich, 2010; Kumar & Gilovich, 2013, 2015). The shared experience of a college education may cost a lot, but, as pundit Art Buchwald said, “The best things in life aren’t things.”
<ul style="list-style-type: none"> • Join the “movement” movement. Aerobic exercise can relieve

mild depression and anxiety as it promotes health and energy. Sound minds reside in sound bodies.

- ***Give your body the sleep it wants.*** Happy people live active lives yet reserve time for renewing sleep and solitude. Sleep debt results in fatigue, diminished alertness, and gloomy moods. If you sleep now, you'll smile later.
- ***Give priority to close relationships.*** Compared with unhappy people, happy people engage in less superficial small talk and more meaningful conversations (Mehl et al., 2010). So resolve to nurture your closest relationships by *not* taking your loved ones for granted: Give them the sort of kindness and affirmation you give others. Relationships matter.
- ***Focus beyond self.*** Reach out to those in need. Perform acts of kindness. Happiness increases helpfulness, but doing good also makes us feel good.
- ***Count your blessings and record your gratitude.*** Keeping a gratitude journal heightens well-being (Davis et al., 2016). Take time to savor positive experiences and achievements, and to appreciate why they occurred (Sheldon & Lyubomirsky, 2012). Express your gratitude to others.
- ***Nurture your spiritual self.*** For many people, faith provides a support community, a reason to focus beyond self, and a sense of purpose and hope. That helps explain why people active in faith communities report greater-than-average happiness and often cope well with crises.

Source: Digested from David G. Myers, *The Pursuit of Happiness* (Harper).

If we can enhance our happiness on an *individual* level, could we use happiness research to refocus our *national* priorities more on the pursuit of happiness? Many psychologists believe we could. Happy societies are not only prosperous, but also places where people trust one another, feel free, and enjoy close relationships (Helliwell et al., 2013; Oishi & Schimmack, 2010a). Thus, in debates about the minimum wage, economic inequality, tax rates,

divorce laws, health care, and city planning, people's psychological well-being can be a consideration. Many political leaders agree: 43 nations have begun measuring their citizens' well-being (Diener et al., 2015). Britain's Annual Population Survey, for example, asks its citizens how satisfied they are with their lives, how worthwhile they judge their lives, and how happy and how anxious they felt yesterday (ONS, 2015).

*"I could cry when I think of the years I wasted
accumulating money, only to learn that my
cheerful disposition is genetic."*

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself

will help you learn and remember the information more effectively thanks to the *testing effect*.

One of the most consistent findings of psychological research is that happy people are also

- a. more likely to express anger.
- b. generally luckier than others.
- c. concentrated in the wealthier nations.
- d. more likely to help others.

_____ psychology is a scientific field of study focused on how humans thrive and flourish.

After moving to a new apartment, you find the street noise irritatingly loud, but after a while it no longer bothers you. This reaction illustrates the

- a. relative deprivation principle.
- b. adaptation-level phenomenon.
- c. feel-good, do-good phenomenon.
- d. catharsis principle.

A philosopher observed that we cannot escape envy, because there will always be someone more successful, more accomplished, or richer with whom to compare ourselves. In psychology, this observation is embodied in the _____ principle.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Stress and Illness

Stress often strikes without warning. Imagine being 21-year-old Ben Carpenter, who experienced the world's wildest and fastest wheelchair ride. As he crossed a street, the light changed and a semitruck started moving into the intersection. When they bumped, Ben's wheelchair handles got stuck in the truck's grille. The driver, who hadn't seen Ben and couldn't hear his cries for help, took off down the highway, pushing the wheelchair at 50 miles per hour until reaching his destination two miles away. "It was very scary," said Ben.

How often do you experience stress in your daily life? Do you feel differently about stressful situations that seem imposed on you (assignments, deadlines, tragic events) than about the stress you impose on yourself (adventures, challenges, happy changes)? As we will see, our definition of events affects our experience of those events and whether we even consider them stressful. In this section, we take a closer look at stress—what it is and how it affects our health and well-being. Let's begin with some basic terms.

Michigan State Police

Extreme stress From the audio recording of a 911 caller reporting Ben Carpenter's distress: "You are not going to believe this. There is a semitruck pushing a guy in a wheelchair on Red Arrow highway!"

Stress: Some Basic Concepts

LOQ 12-15 How does our appraisal of an event affect our stress reaction, and what are the three main types of stressors?

Stress is the process of appraising and responding to a threatening or challenging event (**FIGURE 12.15**). But stress is a slippery concept. We sometimes use the word informally to describe threats or challenges (“Ben was under a lot of stress”), and at other times our responses (“Ben experienced acute stress”). To a psychologist, the terrifying truck ride was a *stressor*. Ben’s physical and emotional responses were a *stress reaction*. And the process by which he related to the threat was *stress*. Stress arises less from events themselves than from how we appraise them (Lazarus, 1998). One person, alone in a house, ignores its creaking sounds and experiences no stress; someone else suspects an intruder and becomes alarmed. One person regards a new job as a welcome challenge; someone else appraises it as risking failure.

stress the process by which we perceive and respond to certain events, called *stressors*, that we appraise as threatening or challenging.

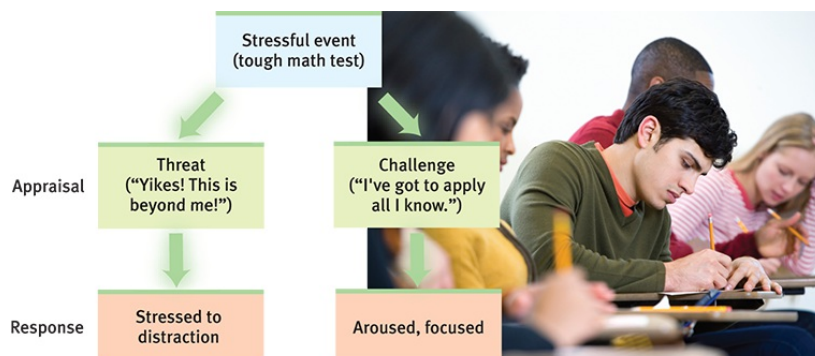

FIGURE 12.15 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Fuse/Getty Images

FIGURE 12.15 Stress appraisal

The events of our lives flow through a psychological filter. How we appraise an event influences how much stress we experience and how effectively we respond.

When short-lived, or when perceived as challenges, stressors can have positive effects. A momentary stress can mobilize the immune system for fending off infections and healing wounds (Segerstrom, 2007). Stress also

arouses and motivates us to conquer problems. In a Gallup World Poll, those who were stressed but not depressed reported being energized and satisfied with their lives. This is the opposite of the lethargy reported by those who were depressed but not stressed (Ng et al., 2009). Championship athletes, successful entertainers, motivated students, and great teachers and leaders all thrive and excel when aroused by a challenge (Blascovich & Mendes, 2010; Wang et al., 2015). In games and athletic contests, the stress of not knowing who will win makes the competition enjoyable (Abuhamdeh et al., 2015). Having conquered cancer or rebounded from a lost job, some people emerge with stronger self-esteem and a deepened spirituality and sense of purpose. Indeed, experiencing some stress early in life builds resilience (Seery, 2011). Adversity can beget growth.

But extreme or prolonged stress can harm us. Stress can trigger risky decisions and unhealthy behaviors (Cohen et al., 2016; Starcke & Brand, 2016). When facing stress, people may smoke or drink. And stress can affect health directly. Pregnant women with overactive stress systems tend to have shorter pregnancies, which pose health risks for their infants (Guardino et al., 2016).

So there is an interplay between our head and our health. That isn't surprising. *Behavioral medicine* research provides a reminder of one of contemporary psychology's overriding themes: *Mind and body interact; everything psychological is simultaneously physiological*. Before exploring that interplay, let's look more closely at stressors and stress reactions.

“Too many parents make life hard for their children by trying, too zealously, to make it easy for them.”

German author Johann Wolfgang von Goethe (1749–1832)

Stressors—Things That Push Our Buttons

Stressors fall into three main types: catastrophes, significant life changes, and daily hassles (including social stress). All can be toxic.

CATASTROPHES Catastrophes are unpredictable large-scale events: earthquakes, floods, wildfires, storms. After such events, damage to

emotional and physical health can be significant. In the four months after Hurricane Katrina, New Orleans' suicide rate reportedly tripled (Saulny, 2006). And in surveys taken in the three weeks after the 9/11 terrorist attacks, 58 percent of Americans said they were experiencing greater-than-average arousal and anxiety (Silver et al., 2002). In the New York City area, people were especially likely to report such symptoms, and sleeping pill prescriptions rose by a reported 28 percent (HMHL, 2002; NSF, 2001). Extensively watching 9/11 television footage predicted worse health outcomes two to three years later (Silver et al., 2013). A similar uptick in health issues, from heart problems to suicides, immediately followed the 2011 terrorist attacks in Norway (Strand et al., 2016).

For those who respond to catastrophes by relocating to another country, the stress may be twofold. The trauma of uprooting and family separation may combine with the challenges of adjusting to a new culture's language, ethnicity, climate, and social norms (Pipher, 2002; Williams & Berry, 1991). In the first half-year, before their morale begins to rebound, newcomers often experience culture shock and deteriorating well-being (Markovizky & Samid, 2008). This *acculturative stress* declines over time, especially when people engage in meaningful activities and connect socially (Kim et al., 2012). In years to come, such relocations may become increasingly common due to climate change.

© Julien Tack

Seismic stress

Unpredictable large-scale events, such as the catastrophic earthquake

that devastated Haiti in 2010 (aftermath shown here), trigger significant levels of stress-related ills. When an earthquake struck Los Angeles in 1994, sudden-death heart attacks increased fivefold. Most occurred in the first two hours after the quake and near its center and were unrelated to physical exertion (Muller & Verrier, 1996).

“You’ve got to know when to hold ’em; know when to fold ’em. Know when to walk away, and know when to run.”

Kenny Rogers, “The Gambler,” 1978

SIGNIFICANT LIFE CHANGES Life transitions—leaving home, having a loved one die, taking on student debt, losing a job, getting divorced—are often keenly felt. Even happy events, such as graduating or getting married, can be stressful life transitions. Many of these changes happen during young adulthood. One survey asked 15,000 Canadian adults whether they were “trying to take on too many things at once.” It found the highest stress levels among young adults (Statistics Canada, 1999). This greater stress of young adulthood also appeared when 650,000 Americans were asked if they had experienced a lot of stress “yesterday” (Newport & Pelham, 2009).

Some psychologists study the health effects of life changes by following people over time. Others compare the life challenges experienced by those who have (or have not) suffered a health problem, such as a heart attack. In such studies, those recently widowed, fired, or divorced have been more vulnerable to disease (Dohrenwend et al., 1982; Sbarra et al., 2015; Strully, 2009). One Finnish study of 96,000 widowed people found that the survivor’s risk of death doubled in the week following a partner’s death (Kaprio et al., 1987). A cluster of crises—losing a job, home, and partner—puts one even more at risk.

DAILY HASSLES AND SOCIAL STRESS Events don’t have to remake our lives to cause stress. Stress also comes from *daily hassles*—dead cell phones, aggravating housemates, and too many things to do (Lazarus, 1990; Pascoe & Richman, 2009; Ruffin, 1993). We might have to give a public speech or do difficult math problems (Balodis et al., 2010; Dickerson & Kemeny, 2004) ([FIGURE 12.16](#)). Some people shrug off such hassles; others cannot. This is especially the case for those who wake up each day facing housing problems, unreliable child care, budgets that won’t stretch to the next

payday, and poor health. Such stressors add up and take a toll on health and well-being (DeLongis et al., 1982, 1988; Piazza et al., 2013; Sin et al., 2015).

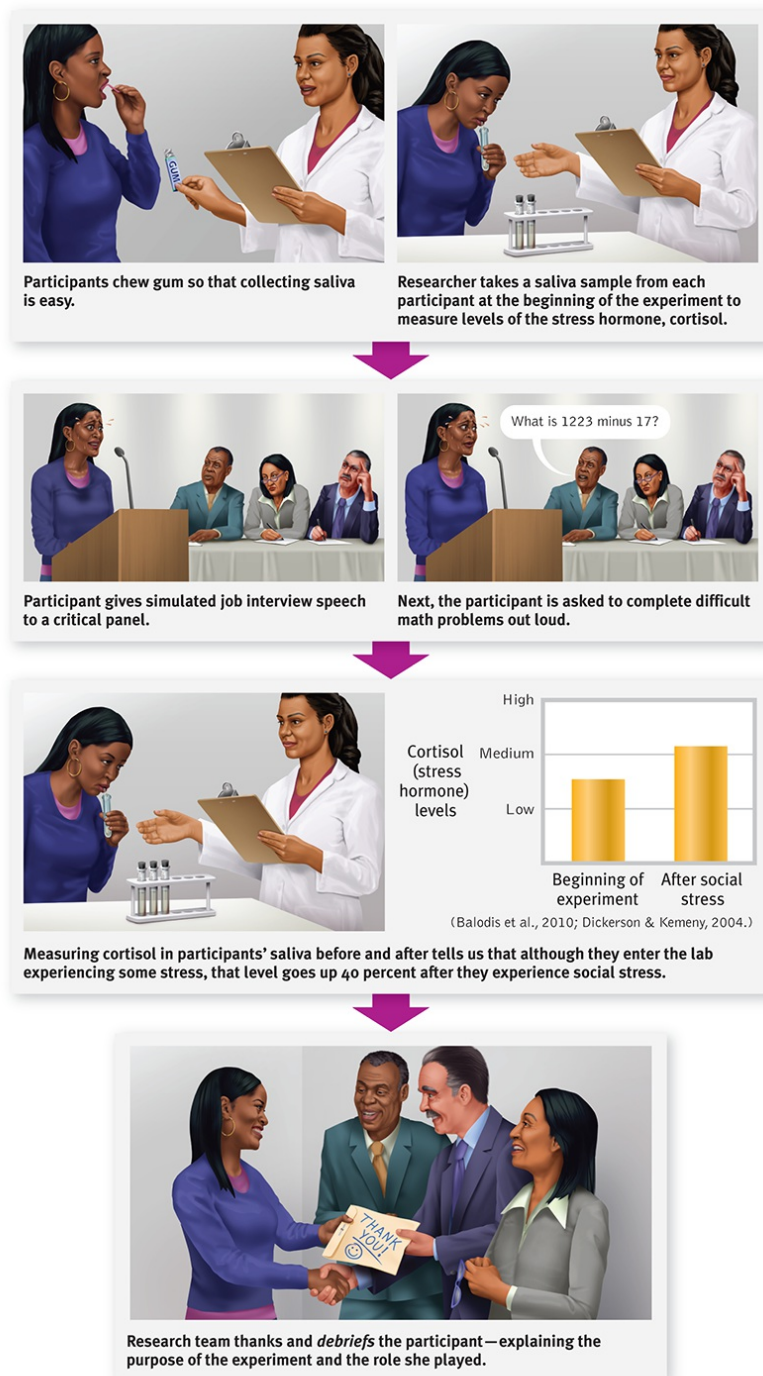

FIGURE 12.16 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.16 Studying stress

Most people experience stress when giving a public speech. To study stress, researchers re-create this type of situation. At the end, they

debrief and reassure each participant.

lisegagne/Getty Images

Don't stop believing you can beat stress

Singing in public can cause stress. In one experiment, participants publicly sang the Journey song “Don’t Stop Believing” (Brooks, 2014). Most people experienced stress, but those who told themselves, “I am excited” felt less stress and earned more performance bonus money. It paid to convert anxiety to excitement.

Daily pressures may be compounded by prejudice against our gender identity, sexual orientation, or ethnicity, which—like other stressors—can have both psychological and physical consequences (Lick et al., 2013; Pascoe & Richman, 2009; Schetter et al., 2013). Thinking that some of the people you encounter each day will dislike, distrust, or doubt you makes daily life stressful. When prolonged, such stress takes a toll on our health. For many African-Americans, for example, stress can lead to unhealthy blood pressure levels and sleep deprivation, which can reduce academic achievement (Levy et al., 2016).

The Stress Response System

LOQ 12-16 How do we respond and adapt to stress?

Medical interest in stress dates back to Hippocrates (460–377 B.C.E.). In the 1920s, Walter Cannon (1929) confirmed that the stress response is part of a

unified mind-body system. He observed that extreme cold, lack of oxygen, and emotion-arousing events all trigger an outpouring of the adrenal stress hormones epinephrine and norepinephrine. When alerted by any of a number of brain pathways, the sympathetic nervous system arouses us, preparing the body for the wonderfully adaptive response that Cannon called *fight or flight*. It increases heart rate and respiration, diverts blood from digestion to the skeletal muscles, dulls feelings of pain, and releases sugar and fat from the body's stores. By fighting or fleeing, we increase our chances of survival.

Since Cannon's time, physiologists have identified an additional stress response system. On orders from the cerebral cortex (via the hypothalamus and pituitary gland), the outer part of the adrenal glands secretes *glucocorticoid* stress hormones such as *cortisol*. The two systems work at different speeds, explained biologist Robert Sapolsky (2003): "In a fight-or-flight scenario, epinephrine is the one handing out guns; glucocorticoids are the ones drawing up blueprints for new aircraft carriers needed for the war effort." The epinephrine guns were firing at high speed during an experiment inadvertently conducted on a British Airways San Francisco to London flight. Three hours after takeoff, a mistakenly played message told passengers the plane was about to crash into the sea. Although the flight crew immediately recognized the error and tried to calm the terrified passengers, several required medical assistance (Associated Press, 1999).

Canadian scientist Hans Selye's (1936, 1976) 40 years of research on stress extended Cannon's findings. His studies of animals' reactions to various stressors, such as electric shock and surgery, helped make stress a major concept in both psychology and medicine. Selye proposed that the body's adaptive response to stress is so general that, like a burglar alarm, it sounds, no matter what intrudes. He named this response the **general adaptation syndrome (GAS)**, and he saw it as a three-phase process ([FIGURE 12.17](#)). Let's say you suffer a physical or an emotional trauma:

FIGURE 12.17 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Sultan Kitaz/Reuters/REUTERS/Newscom; Sebastiano Tomada/Getty Images Reportage

FIGURE 12.17 Selye's general adaptation syndrome

Due to the ongoing conflict, Syria's White Helmets (volunteer rescuers) are perpetually in "alarm reaction" mode, rushing to pull victims from the rubble after each fresh attack. As their resistance depletes, they risk exhaustion.

general adaptation syndrome (GAS) Selye's concept of the body's adaptive response to stress in three phases—alarm, resistance, exhaustion.

- In *Phase 1*, you have an *alarm reaction*, as your sympathetic nervous system is suddenly activated. Your heart rate zooms. Blood is diverted to your skeletal muscles. You feel the faintness of shock. With your resources mobilized, you are now ready to fight back.
- During *Phase 2*, *resistance*, your temperature, blood pressure, and respiration remain high. Your adrenal glands pump hormones into your bloodstream. You are fully engaged, summoning all your resources to meet the challenge. As time passes, with no relief from stress, your body's reserves begin to dwindle.
- You have reached *Phase 3*, *exhaustion*. With exhaustion, you become more vulnerable to illness or even, in extreme cases, collapse and death.

Selye's basic point: Although the human body copes well with temporary stress, prolonged stress can damage it. Severe childhood stress gets under the skin, leading to greater adult stress responses and disease risk (Fagundes & Way, 2014; Hanson et al., 2015; McCrory et al., 2015). In one two-decade-long study, severely stressed Welsh children were three times more likely as

adults to develop heart disease (Ashton et al., 2016). The brain's production of new neurons also slows and some neural circuits degenerate (Dias-Ferreira et al., 2009; Mirescu & Gould, 2006). Former prisoners of war, who experienced constant stress and suffering, have died sooner than their fellow soldiers not taken captive (Solomon et al., 2014).

One study found shortened *telomeres* (DNA pieces at the ends of chromosomes) in those who suffered severe childhood stressors (Puterman et al., 2016). Telomere shortening is a normal part of the aging process; when telomeres get too short, the cell can no longer divide and it ultimately dies. In a study of women who suffered enduring stress as caregivers for children with serious disorders, those who were most stressed had cells that looked a decade older than their chronological age (Epel et al., 2004). Severe stress seems to age people.

We respond to stress in other ways, too. One response is common after a loved one's death: Withdraw. Pull back. Conserve energy. Faced with an extreme disaster, such as a ship sinking, some people become paralyzed by fear. Another, found often among women, is to give and receive support—what's called the [tend-and-befriend](#) response (Lim & DeSteno, 2016; Taylor, 2006; Taylor et al., 2000).

tend and befriend under stress, people (especially women) often provide support to others (tend) and bond with and seek support from others (befriend).

Facing stress, men more often than women tend to withdraw socially, turn to alcohol, or become emotionally insensitive (Bodenmann et al., 2015). Women more often respond to stress by nurturing and banding together. This may in part be due to *oxytocin*, a stress-moderating hormone associated with pair bonding in animals and released, for example, by cuddling, massage, and breast feeding in humans (Campbell, 2010; Taylor, 2006).

“We sleep afraid, we wake up afraid, and leave our homes afraid.”

15-year-old girl's Facebook post, describing her family's daily life in war-torn Yemen (al-Asaadi, 2016).

"You may be suffering from what's known as full-nest syndrome."

RETRIEVAL PRACTICE

RP-10 The stress response system: When alerted to a negative, uncontrollable event, our _____ nervous system arouses us. Heart rate and respiration _____ (increase/decrease). Blood is diverted from digestion to the skeletal _____. The body releases sugar and fat. All this prepares the body for the _____ - _____ - _____ response.

ANSWER: sympathetic; increase; muscles; fight-or-flight

Stress and Vulnerability to Disease

LOQ 12-17 How does stress make us more vulnerable to disease?

It often pays to spend our resources in fighting or fleeing an external threat. But we do so at a cost. When stress is momentary, the cost is small. When

stress persists, the cost may be greater, in the form of lowered resistance to infections and other threats to mental and physical well-being.

To study how stress—and healthy and unhealthy behaviors—influence health and illness, psychologists and physicians created the interdisciplinary field of *behavioral medicine*, integrating behavioral and medical knowledge. [Health psychology](#) provides psychology's contribution to behavioral medicine. A branch of health psychology called [psychoneuroimmunology](#) focuses on mind-body interactions (Kiecolt-Glaser, 2009). This awkward name makes sense when said slowly: Your thoughts and feelings (*psycho*) influence your brain (*neuro*), which influences the endocrine hormones that affect your disease-fighting *immune* system. And this subfield is the study of (*ology*) those interactions.

health psychology a subfield of psychology that provides psychology's contribution to behavioral medicine.

psychoneuroimmunology the study of how psychological, neural, and endocrine processes together affect the immune system and resulting health.

If you've ever had a stress headache, or felt your blood pressure rise with anger, you don't need to be convinced that our psychological states have physiological effects. Stress can even leave you less able to fight off disease because your nervous and endocrine systems influence your immune system (Sternberg, 2009). You can think of the immune system as a complex surveillance system. When it functions properly, it keeps you healthy by isolating and destroying bacteria, viruses, and other invaders. Four types of cells are active in these search-and-destroy missions:

- *B lymphocytes*, which release antibodies that fight bacterial infections;
- *T lymphocytes*, which attack cancer cells, viruses, and foreign substances;
- *macrophage cells* ("big eaters"), which identify, pursue, and ingest harmful invaders and worn-out cells; and
- *natural killer cells* (NK cells), which attack diseased cells (such as

those infected by viruses or cancer). ([FIGURE 12.18](#)).

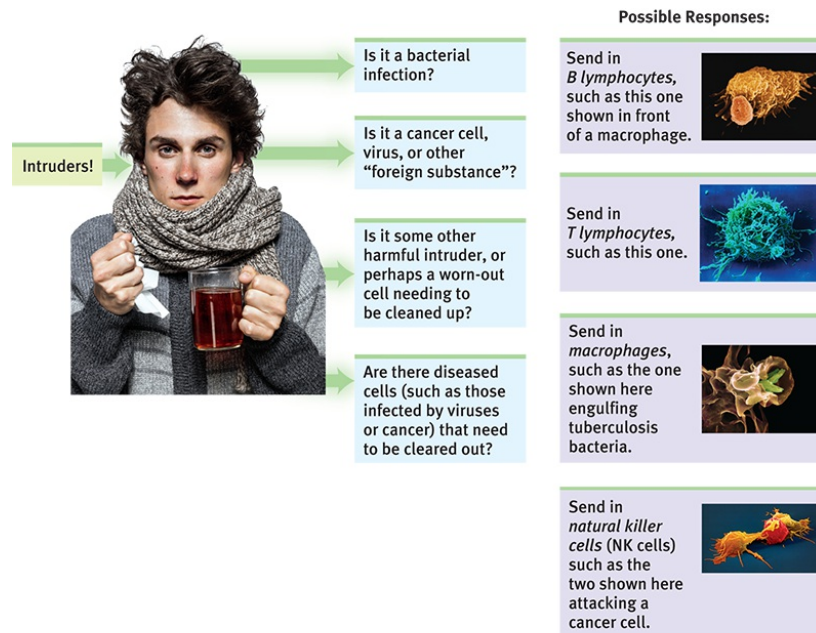

FIGURE 12.18 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Romariolen/Shutterstock; CNRI/Science Source; NIBSC/Science Source; SPL/Science Source;
Eye of Science/Science Source

FIGURE 12.18 A simplified view of immune responses

Your age, nutrition, genetics, body temperature, and stress all influence your immune system's activity. When your immune system doesn't function properly, it can err in two directions:

Responding too strongly, it may attack the body's own tissues, causing an allergic reaction or a self-attacking disease, such as lupus, multiple sclerosis, or some forms of arthritis. Women, who are immunologically stronger than men, are more susceptible to self-attacking diseases (Nussinovitch & Schoenfeld, 2012; Schwartzman-Morris & Putterman, 2012).

Underreacting, the immune system may allow a bacterial infection to flare, a dormant virus to erupt, or cancer cells to multiply. To protect transplanted organs, which the recipient's body treats as foreign invaders, surgeons may deliberately suppress the patient's immune system.

Stress can also trigger immune suppression by reducing the release of disease-fighting lymphocytes. This has been observed when animals were stressed by physical restraints, unavoidable electric shocks, noise, crowding, cold water, social defeat, or separation from their mothers (Maier et al.,

1994). One study monitored immune responses in 43 monkeys over six months (Cohen et al., 1992). Half were left in stable groups. The rest were stressed by being housed with new roommates—3 or 4 new monkeys each month. By the end of the experiment, the socially disrupted monkeys had weaker immune systems.

Human immune systems react similarly. Three examples:

- *Surgical wounds heal more slowly in stressed people.* In one experiment, dental students received punch wounds (precise small holes punched in the skin). Compared with wounds placed during summer vacation, those placed three days before a major exam healed 40 percent more slowly (Kiecolt-Glaser et al., 1998). In other studies, marriage conflict has also slowed punch-wound healing (Kiecolt-Glaser et al., 2005).
- *Stressed people are more vulnerable to colds.* Major life stress increases the risk of a respiratory infection (Pedersen et al., 2010). When researchers dropped a cold virus into people's noses, 47 percent of those living stress-filled lives developed colds ([FIGURE 12.19](#)). Among those living relatively free of stress, only 27 percent did. In follow-up research, the happiest and most relaxed people were likewise markedly less vulnerable to an experimentally delivered cold virus (Cohen et al., 2003, 2006; Cohen & Pressman, 2006).
- *Stress can hasten the course of disease.* As its name tells us, *AIDS* (*acquired immune deficiency syndrome*) is an immune disorder, caused by the *human immunodeficiency virus (HIV)*. Stress cannot give people AIDS. But an analysis of 33,252 participants from around the world found that stress and negative emotions sped the transition from HIV infection to AIDS. And stress predicted a faster decline in those with AIDS (Chida & Vedhara, 2009). The greater the stress that HIV-infected people experienced, the faster their disease progressed.

D. Hurst/Alamy

FIGURE 12.19 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Laurent/Yakou/Science Source

FIGURE 12.19 Stress and colds

People with the highest life stress scores were also most vulnerable when exposed to an experimentally delivered cold virus (Cohen et al., 1991).

The stress effect on immunity makes physiological sense. It takes energy to track down invaders, produce swelling, and maintain fevers. Thus, when diseased, your body reduces its muscular energy output by decreasing activity (and increasing sleep). Stress does the opposite. It creates a competing energy need. During an aroused fight-or-flight reaction, your stress responses divert energy from your disease-fighting immune system and send it to your muscles and brain. This renders you more vulnerable to illness. *The point to remember:* Stress does not make us sick, but it does alter our immune functioning, which leaves us less able to resist infection.

RETRIEVAL PRACTICE

RP-11 The field of _____ studies mind-body interactions, including the effects of psychological, neural, and endocrine functioning on the immune system and

overall health.

ANSWER: psychoneuroimmunology.

RP-12 What general effect does stress have on our health?

ANSWER: Stress tends to reduce our immune system's ability to function properly, so that higher stress generally leads to greater risk of physical illness.

Stress and Cancer

Stress does not create cancer cells. But in a healthy, functioning immune system, lymphocytes, macrophages, and NK cells search out and destroy cancer cells and cancer-damaged cells. If stress weakens the immune system, might this weaken a person's ability to fight off cancer? To explore a possible stress-cancer connection, experimenters have implanted tumor cells in rodents or given them *carcinogens* (cancer-producing substances). They then exposed some rodents to uncontrollable stress, such as inescapable shocks, which weakened their immune systems (Sklar & Anisman, 1981). Stressed rodents, compared with their unstressed counterparts, developed cancer more often, experienced tumor growth sooner, and grew larger tumors.

Does this stress-cancer link also hold with humans? The results are generally the same (Lutgendorf & Andersen, 2015). Some studies find that people are at increased risk for cancer within a year after experiencing depression, helplessness, or bereavement (Chida et al., 2008; Steptoe et al., 2010). In one large Swedish study, the risk of colon cancer was 5.5 times greater among people with a history of workplace stress than among those who reported no such problems. This difference was not due to group differences in age, smoking, drinking, or physical characteristics (Courtney et al., 1993). Not all studies, however, have found a link between stress and human cancer (Coyne et al., 2010; Petticrew et al., 1999, 2002). Concentration camp survivors and former prisoners of war, for example, do not have elevated cancer rates.

One danger in overstating the link between emotions and cancer is that some patients may then blame themselves for their illness: "If only I had been more expressive, relaxed, and hopeful." A corollary danger is a "wellness

macho” among the healthy, who take credit for their “healthy character” and lay a guilt trip on the ill: “She has cancer? That’s what you get for holding your feelings in and being so nice.” Dying thus becomes the ultimate failure.

It’s important enough to repeat: *Stress does not create cancer cells*. At worst, it may affect their growth by weakening the body’s natural defenses against multiplying malignant cells (Lutgendorf et al., 2008; Nausheen et al., 2010; Sood et al., 2010). Although a relaxed, hopeful state may enhance these defenses, we should be aware of the thin line that divides science from wishful thinking. The powerful biological processes at work in advanced cancer are not likely to be completely derailed by avoiding stress or maintaining a relaxed but determined spirit (Anderson, 2002). And that explains why research has consistently indicated that psychotherapy does not extend cancer patients’ survival (Coyne et al., 2007, 2009; Coyne & Tennen, 2010).

For a 7-minute demonstration of the links between stress, cancer, and the immune system, see the **Video: Fighting Cancer—Mobilizing the Immune System**.

Stress and Heart Disease

LOQ 12-18 Why are some of us more prone than others to coronary heart disease?

Imagine this: You wake up each day, eat your breakfast, and check the news. Among the headlines, you see that four 747 jumbo jets crashed again yesterday, killing another 1642 passengers. You finish your breakfast, grab your bag, and head to class. It’s just an average day.

Replace airline crashes with [coronary heart disease](#), the United States’ leading cause of death, and you have re-entered reality. About 610,000 Americans die annually from heart disease (CDC, 2016a). High blood pressure and a family history of the disease increase the risk. So do smoking, obesity, an unhealthy diet, physical inactivity, and a high cholesterol level.

coronary heart disease the clogging of the vessels that nourish the heart muscle; the leading cause of death in many developed countries.

Stress and personality also play a big role in heart disease. The more psychological trauma people experience, the more their bodies generate *inflammation*, which is associated with heart and other health problems, including depression (Haapakoski et al., 2015; O'Donovan et al., 2012). Plucking a hair and measuring its level of cortisol (a stress hormone) can help indicate whether a child has experienced prolonged stress or predict whether an adult will have a future heart attack (Karlén et al., 2015; Pereg et al., 2011; Vliegenthart et al., 2016).

THE EFFECTS OF PERSONALITY, PESSIMISM, AND

DEPRESSION In a classic study, Meyer Friedman, Ray Rosenman, and their colleagues tested the idea that stress increases vulnerability to heart disease by measuring the blood cholesterol level and clotting speed of 40 U.S. male tax accountants at different times of year (Friedman & Ulmer, 1984). From January through March, the test results were completely normal. But as the accountants began scrambling to finish their clients' tax returns before the April 15 filing deadline, their cholesterol and clotting measures rose to dangerous levels. In May and June, with the deadline past, the measures returned to normal. For these men, stress predicted heart attack risk.

So, are some of us at high risk of stress-related coronary heart disease? To answer this question, the researchers launched a *longitudinal* study of more than 3000 healthy men, aged 35 to 59. The researchers interviewed each man for 15 minutes, noting his work and eating habits, manner of talking, and other behavior patterns. Those who seemed the most reactive, competitive, hard-driving, impatient, time-conscious, super-motivated, verbally aggressive, and easily angered they called [Type A](#). The roughly equal number who were more easygoing they called [Type B](#).

Type A Friedman and Rosenman's term for competitive, hard-driving, impatient, verbally aggressive, and anger-prone people.

Type B Friedman and Rosenman's term for easygoing, relaxed people.

“I didn’t give myself cancer.”

Mayor Barbara Boggs Sigmund (1939–1990), Princeton, New Jersey

When organic causes of illness are unknown, it is tempting to invent psychological explanations. Before the germ that causes tuberculosis was discovered, personality explanations of TB were popular (Sontag, 1978).

In both India and the United States, Type A bus drivers are literally hard-driving: They brake, pass, and honk their horns more often than their more easygoing Type B colleagues (Evans et al., 1987).

See the **Video: Longitudinal and Cross-Sectional Studies** for a helpful tutorial animation about these types of research studies.

Nine years later, 257 men had suffered heart attacks, and 69 percent of them were Type A. Moreover, not one of the “pure” Type Bs—the most mellow and laid-back of their group—had suffered a heart attack.

As often happens in science, this exciting discovery provoked enormous public interest. After that initial honeymoon period, researchers wanted to know more. Was the finding reliable? If so, what was the toxic component of the Type A profile: Time-consciousness? Competitiveness? Anger?

More than 700 studies have explored possible psychological correlates or predictors of cardiovascular health (Chida & Hamer, 2008; Chida & Steptoe, 2009). These reveal that Type A’s toxic core is negative emotions—especially the anger associated with an aggressively reactive temperament. When challenged, our active sympathetic nervous system redistributes bloodflow to our muscles, pulling it away from our internal organs. The liver, which normally removes cholesterol and fat from the blood, can’t do its job. Thus, excess cholesterol and fat may continue to circulate in the blood and later get deposited around the heart. Hostility also correlates with other risk factors, such as smoking, drinking, and obesity (Bunde & Suls, 2006). Our mind and heart interact.

“The fire you kindle for your enemy often burns you more than him.”
Chinese proverb

“A cheerful heart is a good medicine, but a downcast spirit dries up the bones.”

Proverbs 17:22

Sean Locke Photography/Shutterstock

© PhotoSpin, Inc/Alamy

Hundreds of other studies of young and middle-aged men and women confirm that people who react with anger over little things are the most coronary-prone. In Western cultures, suppressing negative emotions only heightens the risk (Kitayama et al., 2015; Kupper & Denollet, 2007). Rage “seems to lash back and strike us in the heart muscle” (Spielberger & London, 1982).

Pessimism seems to be similarly toxic (Pänkäläinen et al., 2016). One longitudinal study followed 1306 initially healthy men who a decade earlier had scored as optimists, pessimists, or neither (Kubzansky et al., 2001). Even after adjusting for other risk factors such as smoking, pessimists were more than twice as likely as optimists to develop heart disease ([FIGURE 12.20](#)). Happy and consistently satisfied people tend to be healthy and to outlive their unhappy peers (Boehm et al., 2015b; Diener & Chan, 2011; Gana et al., 2016). Even a big, happy smile predicts longevity, as researchers discovered when they examined the photos of 150 Major League Baseball players who had appeared in the 1952 *Baseball Register* and had died by 2009 (Abel & Kruger, 2010). On average, the nonsmilers had died at 73, compared with an average 80 years for those with a broad, genuine smile. People with big smiles tend to have extensive social networks, which predict longer life (Hertenstein, 2009). Having a happy spouse also predicts better health. Happy you, healthy me (Chopik & O’Brien, 2017).

FIGURE 12.20 Pessimism and heart disease

A Harvard School of Public Health team found pessimistic men at doubled risk of developing heart disease over a 10-year period.

Many studies show that depression can likewise be lethal (Wulsin et al., 1999). In one, nearly 4000 English adults (ages 52 to 79) provided mood reports from a single day. Compared with those in a good mood, those in a blue mood were twice as likely to be dead five years later (Steptoe & Wardle, 2011). In a U.S. survey of 164,102 adults, those who had experienced a heart attack were twice as likely to report also having been depressed at some point in their lives (Witters & Wood, 2015). And in the years following a heart attack, people with high scores for depression were four times more likely than their low-scoring counterparts to develop further heart problems (Frasure-Smith & Lesperance, 2005). Depression is disheartening.

To consider how researchers have studied these issues, engage online with **Immersive Learning: How Would You Know If Stress Increases Risk of Disease?**

STRESS AND INFLAMMATION Depressed people tend to smoke more and exercise less (Whooley et al., 2008). But stress itself is also disheartening: Work stress, involuntary job loss, and trauma-related stress symptoms increase heart disease risk (Allesøe et al., 2010; Gallo et al., 2006; Kubzansky et al., 2009; Slopen et al., 2010).

Jason LaVeris/Getty Images

A broken heart?

The day after the death of her beloved daughter, Carrie Fisher, Debbie Reynolds also died. People wondered: Might grief-related depression and stress hormones have contributed to Reynolds' stroke (Carey, 2016)?

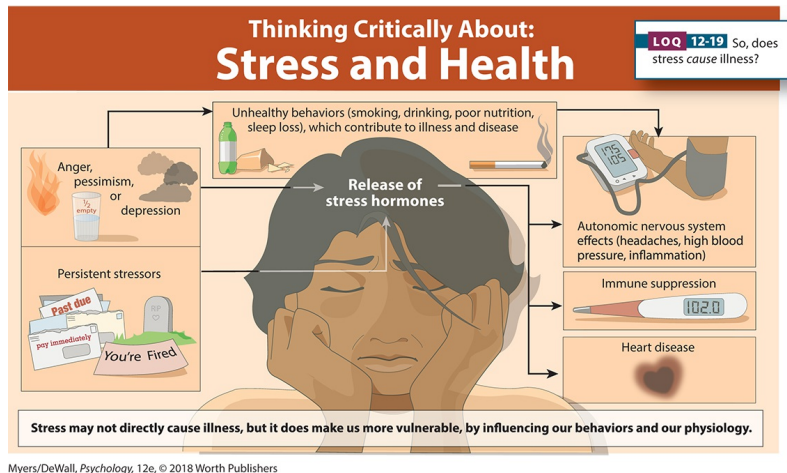

Both heart disease and depression may result when chronic stress triggers blood vessel inflammation (Miller & Blackwell, 2006; Mommersteeg et al., 2016). As we have seen, stress disrupts the body's disease-fighting immune system, enabling the body to focus its energies on fleeing or fighting. People who experience social threats, including children raised in harsh families, are more prone to immune system inflammation responses (Dickerson et al., 2009; Miller & Chen, 2010). So are monkeys that experience the stresses of a low social rank (Snyder-Mackler et al., 2016). Inflammation fights infections. But persistent inflammation can produce problems such as asthma or clogged arteries, and worsen depression.

In many ways stress can affect our health. (See Thinking Critically About: Stress and Health.) The stress-illness connection is a price we pay for the benefits of stress. Stress invigorates our lives by arousing and motivating us. An unstressed life would hardly be challenging or productive.

* * *

Research on stress and health reminds us that psychological states are physiological events that influence other parts of our physiological system. Just pausing to *think* about biting into an orange wedge—imagine the sweet, tangy juice from the pulpy fruit flooding across your tongue—can trigger salivation. As the ancient Indian text the Mahabharata recognized, “Mental

disorders arise from physical causes, and likewise physical disorders arise from mental causes.” There is an interplay between our heads and our health. We are biopsychosocial systems.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

Selye's general adaptation syndrome (GAS) consists of an alarm reaction followed by _____, then

_____.

When faced with stress, women are more likely than men to show a _____-and-_____ response.

The number of short-term illnesses and stress-related psychological disorders was higher than usual in the months following an earthquake. Such findings suggest that

a. daily hassles have adverse health consequences.

- b. experiencing a very stressful event increases a person's vulnerability to illness.
- c. the amount of stress a person feels is directly related to the number of stressors experienced.
- d. daily hassles don't cause stress, but catastrophes can be toxic.

Which of the following is NOT one of the three main types of stressors?

- a. Catastrophes
- b. Significant life changes
- c. Daily hassles
- d. Pessimism

Stress can suppress the immune system by prompting a decrease in the release of _____, the immune cells that ordinarily attack bacteria, viruses, cancer cells, and other foreign substances.

Research has shown that people are at increased risk for cancer a year or so after experiencing depression, helplessness, or bereavement. In describing this link, researchers are quick to point out that

- a. accumulated stress causes cancer.
- b. anger is the negative emotion most closely linked to cancer.
- c. stress does not create cancer cells, but it weakens the body's natural defenses against them.
- d. feeling optimistic about chances of survival increases the likelihood of a cancer patient's recovery.

A Chinese proverb warns, "The fire you kindle for your enemy often burns you more than him." How is this true of Type A individuals?

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Use  **LearningCurve** to create your personalized study plan, which will direct you to the Macmillan resources that will help you most.

Health and Coping

Promoting health begins with implementing strategies that prevent illness and enhance wellness. Traditionally, people have thought about their health only when something goes wrong and they visit a physician. That, say health psychologists, is like ignoring a car's maintenance and going to a mechanic only when the car breaks down. Health maintenance includes alleviating stress, preventing illness, and promoting well-being.

Coping With Stress

LOQ 12-20 In what two ways do people try to alleviate stress?

Stressors are unavoidable. This fact, coupled with the fact that persistent stress correlates with heart disease, depression, and lowered immunity, gives us a clear message. We need to learn to **cope** with the stress in our lives, alleviating it with emotional, cognitive, or behavioral methods. We address some stressors directly, with **problem-focused coping**. If our impatience leads to a family fight, we may go directly to that family member to work things out. We tend to use problem-focused strategies when we feel a sense of control over a situation and think we can change the circumstances, or at least change ourselves to deal with the circumstances more capably. We turn to **emotion-focused coping** when we believe we cannot change a situation. If, despite our best efforts, we cannot get along with that family member, we may relieve stress by reaching out to friends for support and comfort. Sometimes our emotion-focused coping can harm our health, such as when we respond by eating comforting but fattening foods. When challenged, some of us tend to respond with cool problem-focused coping, others with emotion-focused coping (Connor-Smith & Flachsbart, 2007). Our feelings of personal control, our explanatory style, and our supportive connections all influence our ability to cope successfully.

coping alleviating stress using emotional, cognitive, or behavioral methods.

problem-focused coping attempting to alleviate stress directly—by changing the stressor or the way we interact with that stressor.

emotion-focused coping attempting to alleviate stress by avoiding or ignoring a stressor and attending to emotional needs related to our stress reaction.

Perceived Loss of Control

LOQ 12-21 How does a perceived lack of control affect health?

Picture the scene: Two rats receive simultaneous shocks. Only one of them can turn a wheel to stop the shocks. The helpless rat, but not the wheel turner, becomes more susceptible to ulcers and lowered immunity to disease (Laudenslager & Reite, 1984). In humans, too, uncontrollable threats trigger the strongest stress responses (Dickerson & Kemeny, 2004).

Any of us may feel helpless, hopeless, and depressed after experiencing a series of bad events beyond our **personal control**. Martin Seligman and his colleagues have shown that for some animals and people, a series of uncontrollable events creates a state of **learned helplessness**, with feelings of passive resignation (**FIGURE 12.21**). In experiments, dogs were strapped in a harness and given repeated shocks, with no opportunity to avoid them (Seligman & Maier, 1967). Later, when placed in another situation where they *could* escape the punishment by simply leaping a hurdle, the dogs displayed learned helplessness; they cowered as if without hope. Other dogs that had been able to escape the first shocks reacted differently. They had learned they were in control and easily escaped the shocks in the new situation (Seligman & Maier, 1967). People have shown similar patterns of learned helplessness (Abramson et al., 1978, 1989; Seligman, 1975).

personal control our sense of controlling our environment rather than feeling helpless.

learned helplessness the hopelessness and passive resignation an animal or person learns when unable to avoid repeated aversive events.

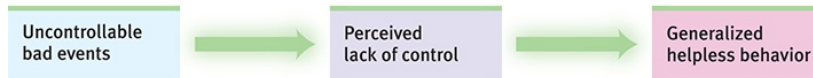

FIGURE 12.21 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.21 Learned helplessness

When animals and people experience no control over repeated bad events, they often learn helplessness.

Perceiving a loss of control, we become more vulnerable to ill health. A famous study of elderly nursing home residents with little perceived control over their activities found that they declined faster and died sooner than those given more control (Rodin, 1986). Workers able to adjust office furnishings and control interruptions and distractions in their work environment have also experienced less stress (O'Neill, 1993). Such findings help explain why British executives have tended to outlive those in clerical or laboring positions, and why Finnish workers with low job stress have been less than half as likely to die of stroke or heart disease as those with a demanding job and little control. The more control workers have, the longer they live (Bosma et al., 1997, 1998; Kivimaki et al., 2002; Marmot et al., 1997).

Control also helps explain a link between economic status and longevity (Jokela et al., 2009). In one study of 843 grave markers in an old cemetery in Glasgow, Scotland, those with the costliest, highest pillars (indicating the most affluence) tended to have lived the longest (Carroll et al., 1994). Likewise, American presidents, who are generally wealthy and well-educated, have had above-average life spans (Olshansky, 2011). Across cultures, high economic status predicts a lower risk of heart and respiratory diseases (Sapolsky, 2005). Wealthy parents also tend to have wealthy, healthy children (Savelieva et al., 2016). With higher economic status come reduced risks of low birth weight, infant mortality, smoking, and violence. Even among other primates, those at the bottom of the social pecking order have been more likely than their higher-status companions to become sick when exposed to a cold-like virus (Cohen et al., 1997).

Why does perceived loss of control predict health problems? Because losing control provokes an outpouring of stress hormones. When rats cannot control shock or when humans or other primates feel unable to control their environment, stress hormone levels rise, blood pressure increases, and immune responses drop (Rodin, 1986; Sapolsky, 2005). Captive animals experience more stress and are more vulnerable to disease than their wild

counterparts (Roberts, 1988). Human studies confirm that stress increases when we lack control. The greater nurses' workload, the higher their cortisol level and blood pressure—but only among nurses who reported little control over their environment (Fox et al., 1993). The crowding in high-density neighborhoods, prisons, and college and university dorms is another source of diminished feelings of control—and of elevated levels of stress hormones and blood pressure (Fleming et al., 1987; Ostfeld et al., 1987).

Increasing control—allowing prisoners to move chairs and to control room lights and the TV; having workers participate in decision making; allowing people to personalize their workspace—has noticeably improved health and morale (Humphrey et al., 2007; Ng et al., 2012; Ruback et al., 1986). In the case of nursing home residents, 93 percent of those who were encouraged to exert more control became more alert, active, and happy (Rodin, 1986). As researcher Ellen Langer concluded, “Perceived control is basic to human functioning” (1983, [p. 291](#)). “For the young and old alike,” she suggested, environments should enhance people’s sense of control over their world. No wonder mobile devices and online streaming, which enhance our control of the content and timing of our entertainment, are so popular. When a massive earthquake hit the Chinese city of Ya’an in 2013, victims took control of the situation by using their mobile devices. Those who sent frequent text messages and used mood-improving apps suffered the least stress (Jia et al., 2016).

Thomas Cordy/The Palm Beach Post/ZUMAPRESS.com

Happy to have control

Working alongside Habitat for Humanity volunteers, this family helped build their own new home.

Google has incorporated these principles effectively. Each week, Google

employees can spend 20 percent of their working time on projects they find personally interesting. This Innovation Time Off program has increased employees' personal control over their work environment, and it has paid off: Gmail was developed this way.

People thrive when they live in conditions of personal freedom and empowerment. At the national level, citizens of stable democracies report higher levels of happiness (Inglehart et al., 2008). Freedom and personal control foster human flourishing. But does ever-increasing choice breed ever-happier lives? Some researchers suggest that today's Western cultures offer an "excess of freedom"—too many choices. The result can be decreased life satisfaction, increased depression, or even behavior paralysis (Schwartz, 2000, 2004). In one study, people offered a choice of one of 30 brands of jam or chocolate were less satisfied with their decision than were others who had chosen from only 6 options (Iyengar & Lepper, 2000). This *tyranny of choice* brings information overload and a greater likelihood that we will feel regret over some of the things we left behind. (Do you, too, ever waste time agonizing over too many choices?)

INTERNAL VERSUS EXTERNAL LOCUS OF CONTROL If experiencing a loss of control can be stressful and unhealthy, do people who generally *perceive* they have control of their lives enjoy better health? Consider your own perceptions of control. Do you believe that your life is beyond your control? That getting a good job depends mainly on being in the right place at the right time? Or do you more strongly believe that you control your own fate? That being a success is a matter of hard work?

Hundreds of studies have compared people who differ in their perceptions of control. On the one side are those who have what psychologist Julian Rotter called an [external locus of control](#), the perception that chance or outside forces control their fate. In one study of more than 1200 Israeli individuals exposed to missile attacks, those with an external locus of control experienced the most *posttraumatic stress disorder* symptoms (Hoffman et al., 2016). On the other side are those who perceive an [internal locus of control](#), who believe they control their own destiny. In study after study, the "internals" have achieved more in school and work, acted more independently, enjoyed better health, and felt less depressed than did the "externals" (Lefcourt, 1982; Ng et al., 2006). In longitudinal research on more than 7500 people, those who had expressed a more internal locus of

control at age 10 exhibited less obesity, lower blood pressure, and less distress at age 30 (Gale et al., 2008). Compared with nonleaders, military and business leaders have lower-than-average levels of stress hormones and report less anxiety, thanks to their greater sense of control (Sherman et al., 2012).

external locus of control the perception that chance or outside forces beyond our personal control determine our fate.

internal locus of control the perception that we control our own fate.

Compared with their parents' generation, more young Americans now express an external locus of control (Twenge et al., 2004). This shift may help explain an associated increase in rates of depression and other psychological disorders in young people (Twenge et al., 2010b).

Another way to say that we believe we are in control of our own life is to say we have *free will*. Studies show that people who believe they have free will learn better, perform better at work, and behave more helpfully (Job et al., 2010; Stillman et al., 2010). They also tend to enjoy making decisions, favor punishing rule breakers, and oppose behavior-restricting government regulations (Clark et al., 2014; Feldman et al., 2014; Hannikainen et al., 2016). These people also tend to demonstrate another type of control known as *willpower* or *self-control*—an important related topic we turn to next.

RETRIEVAL PRACTICE

RP-14 To cope with stress when we feel in control of our world, we tend to use _____(emotion/problem)-focused strategies. To cope with stress when we believe we cannot change a situation, we tend to use _____(emotion/problem)-focused strategies.

ANSWER: problem; emotion

BUILDING SELF-CONTROL

Why is self-control important, and can our self-control be depleted?

When we have a sense of personal control over our lives, we are more likely to develop **self-control**—the ability to control impulses and delay short-term gratification for longer-term rewards. Self-control predicts good health, higher income, and better school performance (Bub et al., 2016; Keller et al., 2016; Moffitt et al., 2011). In studies of American, Asian, and New Zealander children, self-control outdid intelligence test scores in predicting future academic and life success (Duckworth & Seligman, 2005; Poulton et al., 2015; Wu et al., 2016).

self-control the ability to control impulses and delay short-term gratification for greater long-term rewards.

Strengthening self-control is an important key to coping effectively with stress. Doing so requires attention and energy—similar to strengthening a muscle. It's easy to form bad habits, but it takes hard work to break them. With frequent practice in overcoming unwanted urges, people have strengthened their self-control, as seen in their improved self-management of anger, dishonesty, smoking, and impulsive spending (Beames et al., 2017; Wang et al., 2017).

Researchers disagree about the factors that deplete self-control. Self-control varies over time. Like a muscle, it tends to weaken after use, recover after rest, and grow stronger with exercise (Baumeister & Vohs, 2016). Does exercising willpower temporarily deplete the mental energy we need for self-control on other tasks (see Grillon et al., 2015, Luethi et al., 2016, Vohs et al., 2012, versus Hagger et al., 2016)? In one famous experiment, hungry people who had spent some of their willpower resisting the temptation to eat chocolate chip cookies then abandoned a tedious task sooner than did others (Baumeister et al., 1998a). While researchers debate the reliability of this “depletion effect,” the big lesson of self-control research remains: Develop self-discipline, and your self-control can help you have a healthier, happier, and more successful life (Tuk et al., 2015). The next time you face the temptation of studying versus partying, remember that delaying a little fun

now can lead to bigger future rewards.

For more on this topic, engage online with **Assess Your Strengths: How Much Self-Control Do You Have, and Why Is This Worth Working to Increase?**

LatitudeStock - Brian Fairbrother/Getty Images

Extreme self-control

Our ability to exert self-control increases with practice, and some of us have practiced more than others! A number of performing artists make their living as very convincing human statues, as does this actress performing on The Royal Mile in Edinburgh, Scotland.

Explanatory Style: Optimism Versus Pessimism

LOQ 12-23 How does an optimistic outlook affect health and longevity?

In *The How of Happiness* (2008), psychologist Sonja Lyubomirsky tells the true story of Randy. By any measure, Randy has lived a hard life. His dad and best friend both died by suicide. Growing up, his mother's boyfriend treated him poorly. Randy's first wife was unfaithful, and they divorced. Despite these misfortunes, Randy is a happy person whose presence can light up a room. He remarried and enjoys being a stepfather to three boys. His work life is rewarding. Randy says he survived his life challenges by seeing the "silver lining in the cloud."

Randy's story illustrates how our outlook—what we expect from the world—influences how we cope with stress. Pessimists expect things to go badly (Aspinwall & Tedeschi, 2010; Carver et al., 2010; Rasmussen et al., 2009). When bad things happen, pessimists knew it all along. They attribute their poor performance to a basic lack of ability ("I can't do this") or to situations enduringly beyond their control ("There is nothing I can do about it"). Optimists, such as Randy, expect to have more control, to cope better with stressful events, and to enjoy better health (Aspinwall & Tedeschi, 2010; Boehm & Kubzansky, 2012; Hernandez et al., 2015). During a semester's last month, students previously identified as optimistic reported less fatigue and fewer coughs, aches, and pains. And during the stressful first few weeks of law school, those who were optimistic ("It's unlikely that I will fail") enjoyed better moods and stronger immune systems (Segerstrom et al., 1998). Optimists also respond to stress with smaller increases in blood pressure, and they recover more quickly from heart bypass surgery.

Optimistic students have also tended to get better grades because they often respond to setbacks with the hopeful attitude that effort, good study habits, and self-discipline make a difference (Noel et al., 1987; Peterson & Barrett, 1987). When dating couples wrestle with conflicts, optimists and their partners see each other as engaging constructively, and they then tend to feel more supported and satisfied with the resolution and with their relationship (Srivastava et al., 2006). Optimism relates to well-being and success in many places, including China and Japan (Qin & Piao, 2011). Realistic positive expectations fuel motivation and success (Oettingen &

Mayer, 2002).

Consider the consistency and startling magnitude of the optimism and positive emotions factor in several other studies:

- When one research team followed 70,021 nurses over time, they discovered that those scoring in the top quarter on optimism were nearly 30 percent less likely to have died than those scoring in the bottom 25 percent (Kim et al., 2017). Even greater optimism-longevity differences have been found in studies of Finnish men and American Vietnam-era veterans (Everson et al., 1996; Phillips et al., 2009).
- A famous study followed up on 180 Catholic nuns who had written brief autobiographies at about 22 years of age and had thereafter lived similar lifestyles. Those who had expressed happiness, love, and other positive feelings in their autobiographies lived an average 7 years longer than their more dour counterparts (Danner et al., 2001). By age 80, some 54 percent of those expressing few positive emotions had died, as had only 24 percent of the most positive-spirited.
- Optimists not only live long lives, but they maintain a positive view as they approach the end of their lives. One study followed more than 68,000 American women, ages 50 to 79 years, for nearly two decades (Zaslavsky et al., 2015). As death grew nearer, the optimistic women tended to feel more life satisfaction than did the pessimistic women.

Sam Gross The New Yorker Collection/The Cartoon Bank

"We just haven't been flapping them hard enough."

Positive expectations often motivate eventual success.

"The optimist proclaims we live in the best of all possible worlds; and the pessimist fears this is true."

James Branch Cabell, *The Silver Stallion*, 1926

Optimism runs in families, so some people truly are born with a sunny, hopeful outlook. If one identical twin is optimistic, the other often will be as well (Bates, 2015; Mosing et al., 2009). One genetic marker of optimism is a gene that enhances the social-bonding hormone *oxytocin* (Saphire-Bernstein et al., 2011).

The good news is that all of us, even the most pessimistic, can learn to become more optimistic. Compared with a control group of pessimists who simply kept diaries of their daily activities, pessimists in a skill-building group—who learned ways of seeing the bright side of difficult situations and of viewing their goals as achievable—reported lower levels of depression (Sergeant & Mongrain, 2014). Optimism is the light bulb that can brighten anyone's mood.

Social Support

LOQ 12-24 How does social support promote good health?

Social support—feeling liked and encouraged by intimate friends and family—promotes both happiness and health. In massive investigations, some following thousands of people for several years, close relationships have predicted happiness and health in both individualist and collectivist cultures (Brannan et al., 2013; Gable et al., 2012; Rueger et al., 2016). People are less likely to die early if supported by close relationships (Shor et al., 2013). When Brigham Young University researchers combined data from 70 studies of 3.4 million people worldwide, they confirmed a striking effect of social support (Holt-Lunstad et al., 2015). Compared with those who had ample social connections, those who were socially isolated or felt lonely had a 30 percent greater death rate during the 7-year study period. Social isolation's association with risk of death is equivalent to smoking (Holt-Lunstad et al., 2010).

To combat social isolation, we need to do more than collect lots of acquaintances. We need people who genuinely care about us (Cacioppo et al., 2014; Hawkey et al., 2008). Some fill this need by connecting with friends, family, co-workers, members of a faith community, or other support groups. Others connect in positive, happy, supportive marriages. One seven-decade-long study found that at age 50, healthy aging was better predicted by a good marriage than by a low cholesterol level (Vaillant, 2002). On the flip side, divorce predicts poor health. In one analysis of 32 studies involving more than 6.5 million people, divorced people were 23 percent more likely to die early (Sbarra et al., 2011). But it's less marital status than marital *quality* that predicts health—to about the same extent as a healthy diet and physical activity do (Robles, 2015; Robles et al., 2014).

What explains the link between social support and health? Are middle-aged and older adults who live alone more likely to smoke, be obese, and have high cholesterol—and therefore to have a doubled risk of heart attacks (Nielsen et al., 2006)? Or are healthy people simply more sociable? Possibly. But research suggests that social support does have health benefits.

Rubberball/Mark Andersen/Getty Images

Laughter among friends is good medicine

Laughter arouses us, massages muscles, and then leaves us feeling relaxed (Robinson, 1983). Humor (though not hostile sarcasm) may defuse stress, ease pain, and strengthen immune activity (Ayan, 2009; Berk et al., 2001; Dunbar et al., 2011; Kimata, 2001). People who laugh a lot have also tended to have lower rates of heart disease (Clark et al., 2001).

Social support calms us and reduces blood pressure and stress hormones (Baron et al., 2016; Hostinar et al., 2014; Uchino et al., 1996, 1999). To see if social support might calm people's response to threats, one research team subjected happily married women, while lying in an fMRI machine, to the threat of electric shock to an ankle (Coan et al., 2006). During the experiment, some women held their husband's hand. Others held the hand of an unknown person or no hand at all. While awaiting the occasional shocks, women holding their husband's hand showed less activity in threat-responsive areas. This soothing benefit was greatest for those reporting the highest-quality marriages. People with supportive marriages also had below-average stress hormone levels 10 years later (Slatcher et al., 2015). Even

animal support, such as a companionable pet, helps buffer stress (Siegel, 1990).

Photos.com/Getty Images

Pets are friends, too

Pets can provide social support. Having a pet may increase the odds of survival after a heart attack, relieve depression among people with AIDS, and lower blood pressure and other coronary risk factors (Allen, 2003; McConnell et al., 2011; Wells, 2009). To lower blood pressure, pets are no substitute for effective drugs and exercise. But for people who enjoy animals, and especially for those who live alone, pets are a healthy pleasure (Allen, 2003).

“Woe to one who is alone and falls and does not have another to help.”

Ecclesiastes 4:10

Social support fosters stronger immune functioning. Volunteers in studies of resistance to cold viruses showed this effect (Cohen, 2004; Cohen et al., 1997). Healthy volunteers inhaled nasal drops laden with a cold virus and were quarantined and observed for five days. (In these experiments, more than 600 volunteers received \$800 each to endure this experience.) Age, race, sex, and health habits being equal, those with close social ties were least likely to catch a cold. People whose daily life included frequent hugs likewise experienced fewer cold symptoms and less symptom severity (Cohen et al.,

2015). The cold fact is that the effect of social ties is nothing to sneeze at!

Close relationships give us an opportunity for “open heart therapy”—a chance to confide painful feelings (Frattaroli, 2006). Talking about a stressful event can temporarily arouse us, but in the long run it calms us (Lieberman et al., 2007; Mendolia & Kleck, 1993; Niles et al., 2015). In one study, 33 Holocaust survivors spent two hours recalling their experiences, many in intimate detail never before disclosed (Pennebaker et al., 1989). In the weeks following, most watched a video of their recollections and showed it to family and friends. Those who were most self-disclosing had the most improved health 14 months later. In another study, of surviving spouses of people who had committed suicide or died in car accidents, those who bore their grief alone had more health problems than those who shared it with others (Pennebaker & O’Heeron, 1984). Confiding is good for the body and the soul.

Suppressing emotions can be detrimental to physical health. When psychologist James Pennebaker (1985) surveyed more than 700 undergraduate women, some reported a traumatic sexual experience in childhood. The sexually abused women—especially those who had kept their secret to themselves—reported more headaches and stomach ailments than did other women who had experienced nonsexual traumas, such as parental death or divorce. Another study, of 437 Australian ambulance drivers, confirmed the ill effects of suppressing one’s emotions after witnessing traumas (Wastell, 2002).

Even writing about personal traumas in a diary can help (Burton & King, 2008; Kállay, 2015; Lyubomirsky et al., 2006). In an analysis of 633 trauma victims, writing therapy was as effective as psychotherapy in reducing psychological trauma (van Emmerik et al., 2013). In another experiment, volunteers who wrote trauma diaries had fewer health problems during the ensuing 4 to 6 months (Pennebaker, 1990). As one participant explained, “Although I have not talked with anyone about what I wrote, I was finally able to deal with it, work through the pain instead of trying to block it out. Now it doesn’t hurt to think about it.”

Baby Blues: © 2010 Baby Blues Partnership Distributed by King Features Syndicate, Inc.

If we are aiming to exercise more, drink less, quit smoking, or be a healthy weight, our social ties can tug us away from or toward our goal. If you are trying to achieve some goal, think about whether your social network will help or hinder you.

Reducing Stress

Having a sense of control, developing more optimistic thinking, and building social support can help us *experience* less stress and thus improve our health. Moreover, these factors interrelate: People who have been upbeat about themselves and their future have tended also to enjoy health-promoting social ties (Stinson et al., 2008). But sometimes we cannot alleviate stress and simply need to *manage* our stress. Aerobic exercise, relaxation, meditation, and spiritual communities may help us gather inner strength and lessen stress effects.

Aerobic Exercise

LOQ 12-25 How effective is aerobic exercise as a way to manage stress and improve well-being?

Aerobic exercise is sustained, oxygen-consuming, exertion—such as jogging, swimming, or biking—that increases heart and lung fitness. It’s hard to find bad things to say about exercise. Estimates vary, but moderate exercise adds to your quantity *and* quality of life, with more energy, better mood, and stronger relationships (Flueckiger et al., 2016; Hogan et al., 2015; Seligman, 1994; Wang et al., 2011).

aerobic exercise sustained exercise that increases heart and lung fitness; also helps alleviate depression and anxiety.

Exercise helps fight heart disease by strengthening the heart, increasing bloodflow, keeping blood vessels open, and lowering both blood pressure and the blood pressure reaction to stress (Ford, 2002; Manson, 2002). Compared with inactive adults, people who exercise suffer about half as many heart attacks (Evenson et al., 2016; Visich & Fletcher, 2009). Exercise makes the muscles hungry for the fats that, if not used by the muscles, contribute to clogged arteries (Barinaga, 1997). In one study of over 650,000 American adults, walking 150 minutes per week predicted living seven years longer than nonexercisers (Moore et al., 2012). A follow-up study of 1.44 million Americans and Europeans found that exercise predicted “lower risks of many cancer types” (Moore et al., 2016). Regular exercise in later life also predicts better cognitive functioning and reduced risk of neurocognitive disorder and Alzheimer’s disease (Kramer & Erickson, 2007).

The genes passed down to us from our distant ancestors were those that enabled the physical activity essential to hunting, foraging, and farming (Raichlen & Polk, 2013). In muscle cells, those genes, when activated by exercise, respond by producing proteins. In the modern inactive person, these genes produce lower quantities of proteins and leave us susceptible to more than 20 chronic diseases, such as type 2 diabetes, coronary heart disease, stroke, and cancer (Booth & Neuffer, 2005). Inactivity is thus potentially toxic. Physical activity can weaken the influence of some genetic risk factors. In one analysis of 45 studies, the risk of obesity fell by 27 percent (Kilpeläinen et al., 2012).

Does exercise also boost the spirit? In a 21-country survey of university students, physical exercise was a strong and consistent predictor of life satisfaction (Grant et al., 2009). Americans, Canadians, and Britons who do aerobic exercise at least three times a week manage stress better, exhibit more self-confidence, feel more vigor, and feel less depressed and fatigued than their inactive peers (Rebar et al., 2015; Smits et al., 2011). Going from active exerciser to couch potato can increase the likelihood of depression—by 51 percent in two years for the women in one study (Wang et al., 2011). Among people with depression, getting off the couch and into a more physically

active life reduces depressive symptoms (Kvam et al., 2016; Snippe et al., 2016). “Exercise has a large and significant antidepressant effect,” concluded one digest of 25 controlled studies (Schuch et al., 2016a).

But we could state this observation another way: Stressed and depressed people exercise less. These findings are correlations, and cause and effect are unclear. To sort out cause and effect, researchers experiment. They randomly assign stressed, depressed, or anxious people either to an aerobic exercise group or to a control group. Next, they measure whether aerobic exercise (compared with a control activity not involving exercise) produces a change in stress, depression, anxiety, or some other health-related outcome. One classic experiment randomly assigned mildly depressed female college students to three groups. One-third participated in a program of aerobic exercise. Another third took part in a program of relaxation exercises. The remaining third (the control group) formed a no-treatment group (McCann & Holmes, 1984). As [FIGURE 12.22](#) shows, 10 weeks later, the women in the aerobic exercise program reported the greatest decrease in depression. Many had, quite literally, run away from their troubles.

The mood boost

When energy or spirits are sagging, few things reboot the day better than exercising, as I [DM] can confirm from my noontime biking and basketball, and as I [ND] can confirm from my running.

Dozens of other experiments and longitudinal studies confirm that exercise prevents or reduces depression and anxiety (Catalan-Matamoros et al., 2016; Conn, 2010; Pinto Pereira et al., 2014). When experimenters randomly assigned depressed people to an exercise group, an antidepressant group, or a placebo pill group, exercise diminished depression as effectively as antidepressants—and with longer-lasting effects (Hoffman et al., 2011).

Vigorous exercise provides a substantial and immediate mood boost (Watson, 2000). Even a 10-minute walk stimulates 2 hours of increased well-being by raising energy levels and lowering tension (Thayer, 1987, 1993). Exercise works its magic in several ways. It increases arousal, thus counteracting depression's low arousal state. It enables muscle relaxation and sounder sleep. Like an antidepressant drug, it orders up mood-boosting chemicals from our body's internal pharmacy—neurotransmitters such as norepinephrine, serotonin, and the endorphins (Jacobs, 1994; Salmon, 2001). What is more, toned muscles filter out depression-causing toxins (Agudelo et al., 2014). Exercise also fosters *neurogenesis*. In mice, exercise causes the brain to produce a molecule that stimulates the production of new, stress-resistant neurons (Hunsberger et al., 2007; Reynolds, 2009; van Praag, 2009).

On a simpler level, the sense of accomplishment and improved physique and body image that often accompany a successful exercise routine may enhance one's self-image, leading to a better emotional state. Frequent

exercise is like a drug that prevents and treats disease, increases energy, calms anxiety, and boosts mood—a drug we would all take, if available. Yet few people (only 1 in 4 in the United States) take advantage of it (Mendes, 2010).

Relaxation and Meditation

LOQ 12-26 In what ways might relaxation and meditation influence stress and health?

Knowing the damaging effects of stress, could we learn to counteract our stress responses by altering our thinking and lifestyle? In the late 1960s, psychologists began experimenting with *biofeedback*, a system of recording, amplifying, and feeding back information about subtle physiological responses, many controlled by the autonomic nervous system. Biofeedback instruments mirror the results of a person's own efforts, enabling the person to learn which techniques do (or do not) control a particular physiological response. After a decade of study, however, the initial claims for biofeedback seemed overblown and oversold (Miller, 1985). In 1995, a National Institutes of Health panel declared that biofeedback works best on tension headaches.

Simple methods of relaxation, which require no expensive equipment, produce many of the results biofeedback once promised. [Figure 12.22](#) pointed out that aerobic exercise reduces depression. But did you notice in that figure that depression also decreased among women in the relaxation treatment group? More than 60 studies have found that relaxation procedures can also help alleviate headaches, hypertension, anxiety, and insomnia (Nestoriuc et al., 2008; Stetter & Kupper, 2002).

Such findings would not surprise Meyer Friedman, Ray Rosenman, and their colleagues. They tested relaxation in a program designed to help *Type A* heart attack survivors (who are more prone to heart attacks than their *Type B* peers) reduce their risk of future attacks. They randomly assigned hundreds of middle-aged men to one of two groups. The first group received standard advice from cardiologists about medications, diet, and exercise habits. The second group received similar advice, but they also were taught ways of modifying their lifestyles. They learned to slow down and relax by walking, talking, and eating more slowly. They learned to smile at others and laugh at themselves. They learned to admit their mistakes, to take time to enjoy life,

and to renew their religious faith. The training paid off ([FIGURE 12.23](#)). During the next three years, those who learned to modify their lifestyle had half as many repeat heart attacks as did the first group. This, wrote the exuberant Friedman, was an unprecedented, spectacular reduction in heart attack recurrence. A smaller-scale British study spanning 13 years similarly showed a halved death rate among high-risk people trained to alter their thinking and lifestyle (Eysenck & Grossarth-Maticek, 1991). After suffering a heart attack at age 55, Friedman started taking his own behavioral medicine—and lived to age 90 (Wargo, 2007).

FIGURE 12.23 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
Data from Friedman & Ulmer, 1984

FIGURE 12.23 Recurrent heart attacks and lifestyle modification

The San Francisco Recurrent Coronary Prevention Project offered counseling from a cardiologist to survivors of heart attacks. Those who were also guided in modifying their Type A lifestyle suffered fewer repeat heart attacks.

Time may heal all wounds, but relaxation can help speed that process. In one study, surgery patients were randomly assigned to two groups. Both groups received standard treatment, but the second group also experienced a 45-minute relaxation exercise and received relaxation recordings to use before and after surgery. A week after surgery, patients in the relaxation group reported lower stress and showed better wound healing (Broadbent et al., 2012).

AP

Furry friends for finals week

Some schools bring cuddly critters on campus for finals week as a way to help students relax and bring disruptive stress levels down. This student at Emory University is relaxing with dogs and puppies. Other schools offer petting zoos or encourage instructors to bring in their own pets that week.

Meditation is a modern practice with a long history. In many world religions, meditation has been used to reduce suffering and improve

awareness, insight, and compassion. Numerous studies have confirmed the psychological benefits of different types of meditation (Goyal et al., 2014; Rosenberg et al., 2015; Sedlmeier et al., 2012). These types include [mindfulness meditation](#), which today has found a new home in stress management programs. If you were taught this practice, you would relax and silently attend to your inner state, without judging it (Brown et al., 2016; Kabat-Zinn, 2001). You would sit down, close your eyes, and mentally scan your body from head to toe. Zooming in on certain body parts and responses, you would remain aware and accepting. You would also pay attention to your breathing, attending to each breath as if it were a material object.

mindfulness meditation a reflective practice in which people attend to current experiences in a nonjudgmental and accepting manner.

“Sit down alone and in silence. Lower your head, shut your eyes, breathe out gently, and imagine yourself looking into your own heart. . . . As you breathe out, say ‘Lord Jesus Christ, have mercy on me.’ . . . Try to put all other thoughts aside. Be calm, be patient, and repeat the process very frequently.”

Gregory of Sinai, died 1346

Practicing mindfulness may lessen anxiety and depression (Goyal et al., 2014). In one study of 1140 people, some received mindfulness-based therapy for several weeks. Others did not. Levels of anxiety and depression were lower among those who received the therapy (Hofmann et al., 2010). Mindfulness practices have also been linked with improved sleep, interpersonal relationships, and immune system functioning (Gong et al., 2016; Rosenkranz et al., 2013; Sedlmeier et al., 2012; Tang et al., 2007). Just a few minutes of daily mindfulness meditation is enough to improve concentration and decision making (Hafenbrack et al., 2014; Rahl et al., 2016).

So, what’s going on in the brain as we practice mindfulness? Correlational and experimental studies offer three explanations. Mindfulness

- *strengthens connections among regions in our brain.* The affected regions are those associated with focusing our attention, processing what we see and hear, and being reflective and aware (Berkovich-Ohana et al., 2014; Ives-Deliperi et al., 2011; Kilpatrick et al., 2011).
- *activates brain regions associated with more reflective awareness* (Davidson et al., 2003; Way et al., 2010). When labeling emotions, mindful people show less activation in the amygdala, a brain region associated with fear, and more activation in the prefrontal cortex, which aids emotion regulation (Creswell et al., 2007; Gotink et al., 2016).
- *calms brain activation in emotional situations.* This lower activation was clear in one study in which participants watched two movies—one sad, one neutral. Those in the control group, who were not trained in mindfulness, showed strong differences in brain activation when watching the two movies. Those who had received mindfulness training showed little change in brain response to the two movies (Farb et al., 2010). Emotionally unpleasant images also trigger weaker electrical brain responses in mindful people than in their less mindful counterparts (Brown et al., 2013). A mindful brain is strong, reflective, and calm.

Exercise and meditation are not the only routes to healthy relaxation. Massage helps relax both premature infants and those suffering pain, and it relaxes muscles and helps reduce depression (Hou et al., 2010).

And then there are the mystics who seek to use the mind's power to enable novocaine-free cavity repair. Their aim: transcend dental medication.

Faith Communities and Health

LOQ 12-27 What is the faith factor, and what are some possible explanations for the link between faith and health?

A wealth of studies—some 1800 of them in the twenty-first century's first decade alone—has revealed another curious correlation, called the *faith*

factor (Koenig et al., 2012). Religiously active people tend to live longer than those who are not religiously active. One such study compared the death rates for 3900 people living in two Israeli communities. The first community contained 11 religiously orthodox collective settlements; the second contained 11 matched, nonreligious collective settlements (Kark et al., 1996). Over a 16-year period, “belonging to a religious collective was associated with a strong protective effect” not explained by age or economic differences. In every age group, religious community members were about half as likely to have died as were their nonreligious counterparts. This difference is roughly comparable to the gender difference in mortality. A more recent study followed 74,534 nurses over 20 years. When controlling for various health risk factors, those who attended religious services more than weekly were a third less likely to have died than were nonattenders (Li et al., 2016).

How should we interpret such findings? Correlations are not cause-effect statements, and they leave many factors uncontrolled (Sloan, 2005; Sloan et al., 1999, 2000, 2002). Here is another possible interpretation: Women are more religiously active than men, and women outlive men. Might religious involvement merely reflect this gender-longevity link? Apparently not. One 8-year National Institutes of Health study followed 92,395 women, ages 50 to 79. After controlling for many factors, researchers found that women attending religious services at least weekly experienced an approximately 20 percent reduced risk of death during the study period (Schnall et al., 2010). Moreover, the association between religious involvement and life expectancy is also found among men (Benamins et al., 2010; McCullough et al., 2000; McCullough & Laurenceau, 2005). A 28-year study that followed 5286 Californians found that, after controlling for age, gender, ethnicity, and education, frequent religious attenders were 36 percent less likely to have died in any year ([FIGURE 12.24](#)). In another 8-year controlled study of more than 20,000 people (Hummer et al., 1999), this effect translated into a life expectancy of 83 years for those frequently attending religious services and only 75 years for nonattenders.

FIGURE 12.24 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.24 Predictors of longer life: Not smoking, frequent exercise, and regular religious attendance

One 28-year study followed 5286 Alameda, California, adults (Oman et al., 2002; Strawbridge, 1999; Strawbridge et al., 1997). Controlling for age and education, the researchers found that not smoking, regular exercise, and religious attendance all predicted a lowered risk of death in any given year. Women attending weekly religious services, for example, were only 54 percent as likely to die in a typical study year as were nonattenders.

These correlational findings do not indicate that nonattenders can suddenly add 8 years of life if they start attending services and change nothing else. Nevertheless, the findings do indicate that religious involvement, like nonsmoking and exercise, is a *predictor* of health and longevity. Research points to three possible explanations for the religiosity-longevity correlation ([FIGURE 12.25](#)):

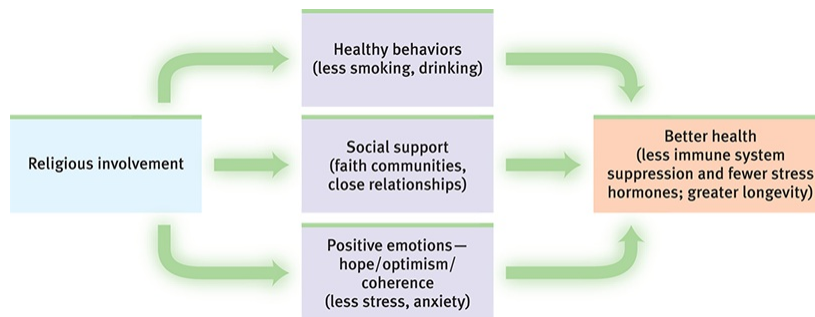

FIGURE 12.25 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

FIGURE 12.25 Possible explanations for the correlation between religious involvement and health/longevity

- *Healthy behaviors* Religion promotes self-control (DeWall et al., 2014; McCullough & Willoughby, 2009). And that helps explain why religiously active people tend to smoke and drink much less and to have healthier lifestyles (Islam & Johnson, 2003; Koenig & Vaillant, 2009; Masters & Hooker, 2013). In one Gallup survey of 550,000 Americans, 15 percent of the very religious were smokers, as were 28 percent of the nonreligious (Newport et al., 2010). But such lifestyle differences are not great enough to explain the dramatically reduced mortality in the Israeli religious settlements. In American studies, too, about 75 percent of the longevity difference remained when researchers controlled for unhealthy behaviors, such as inactivity and smoking (Musick et al., 1999).
- *Social support* Could social support explain the faith factor (Ai et al., 2007; Kim-Yeary et al., 2012)? Faith is often a communal experience. To belong to a faith community is to participate in a support network. Religiously active people are there for one another when misfortune strikes. Moreover, religion encourages marriage, another predictor of health and longevity. In the Israeli religious settlements, for example, divorce has been almost nonexistent. In the 20-year nurses study, social support was the biggest contributor to the religiosity factor—explaining a fourth of its effect.
- *Positive emotions* Even after controlling for social support, gender, unhealthy behaviors, and preexisting health problems, the mortality studies have found that religiously engaged people tend to live longer (Chida et al., 2009). Researchers speculate that religiously active people may benefit from a stable, coherent worldview, a

sense of hope for the long-term future, feelings of ultimate acceptance, and the relaxed meditation of prayer or other religious observance. These intervening variables may also help to explain why the religiously active have had healthier immune functioning, fewer hospital admissions, and, for people with AIDS, fewer stress hormones and longer survival (Ironson et al., 2002; Koenig & Larson, 1998; Lutgendorf et al., 2004).

RETRIEVAL PRACTICE

RP-15 What are some of the tactics we can use to successfully manage the stress we cannot avoid?

ANSWER: Aerobic exercise, relaxation procedures, mindfulness meditation, and religious engagement

To check your understanding of the best ways to handle stress, engage online with **Concept Practice: Methods of Managing Stress**.

MASTER THE MATERIAL

Test yourself repeatedly throughout your studies. This will not only help you figure out what you know and don't know; the testing itself will help you learn and remember the information more effectively thanks to the *testing effect*.

When faced with a situation over which you feel you have little control, you are more likely to turn to _____

(emotion/problem)-focused coping.

Seligman's research showed that a dog will respond with learned helplessness if it has received repeated shocks and has had

- a. the opportunity to escape.
- b. no control over the shocks.
- c. pain or discomfort.
- d. no food or water prior to the shocks.

When elderly patients take an active part in managing their own care and surroundings, their morale and health tend to improve. Such findings indicate that people do better when they experience an _____ (internal/external) locus of control.

People who have close relationships are less likely to die prematurely than those who do not, supporting the idea that

- a. social ties can be a source of stress.
- b. gender influences longevity.
- c. Type A behavior is responsible for many premature deaths.
- d. social support has a beneficial effect on health.

Because it triggers the release of mood-boosting neurotransmitters such as norepinephrine, serotonin, and the endorphins, _____ exercise raises energy levels and helps alleviate depression and anxiety.

Research on the faith factor has found that

- a. pessimists tend to be healthier than optimists.
- b. our expectations influence our feelings of stress.
- c. religiously active people tend to outlive those who are not religiously active.
- d. religious engagement promotes social isolation and repression.

Answers are a click away in the e-book, and available in [Appendix D](#) at the back of the printed text.

Conflict and Peacemaking

Dirk Willems faced a moment of decision in 1569. Threatened with torture and death as a member of a persecuted religious minority, he escaped from his Asperen, Holland, prison and fled across an ice-covered pond. His stronger and heavier jailer pursued him but fell through the ice and, unable to climb out, pleaded for help.

With his freedom in front of him, Willems acted with ultimate selflessness. He turned back and rescued his pursuer, who, under orders, took him back to captivity. A few weeks later Willems was condemned to be “executed with fire, until death ensues.” For his martyrdom, present-day Asperen has named a street in honor of its folk hero (Toews, 2004).

What drives people to feel contempt for minority-group members, such as Dirk Willems, and to act so spitefully? What motivates people, such as his jailer, to carry out unfair orders? And what inspired the selflessness of Willems’ response, and of so many who have died trying to save others? Indeed, what motivates any of us who volunteer kindness and generosity toward others?

We are social animals. As novelist Herman Melville remarked, “We cannot live for ourselves alone. Our lives are connected by a thousand invisible threads.” Social psychologists explore these connections by scientifically studying how we think about, influence, and relate to one another.

Social Thinking

LOQ

LEARNING OBJECTIVE QUESTION

13-1

What do social psychologists study? How do we tend to explain others' behavior and our own?

Personality psychologists focus on the person. They study the personal traits and dynamics that explain why, in a given situation, *different people* act differently. (Would you have acted as Willems did, helping the jailer out of the icy water?) [Social psychologists](#) focus on the situation. They study the social influences that explain why *the same person* acts differently in *different situations*. (Might the jailer have acted differently—opting not to march Willems back to jail—under differing circumstances?)

social psychology the scientific study of how we think about, influence, and relate to one another.

Unlike sociology, which studies societies and social groupings, social psychologists focus more on how *individuals* view and affect one another.

Mennonite Library and Archives/Bethel College

An etching of Dirk Willems by Dutch artist Jan Luyken (from *The Martyrs Mirror*, 1685)

The Fundamental Attribution Error

Our social behavior arises from our social cognition. Especially when the unexpected occurs, we want to understand and explain why people act as they do. After studying how people explain others' behavior, Fritz Heider (1958) proposed an [attribution theory](#): We can attribute the behavior to the person's stable, enduring traits (a *dispositional attribution*), or we can attribute it to the situation (a *situational attribution*).

attribution theory the theory that we explain someone's behavior by crediting either the situation or the person's disposition.

For example, in class, we notice that Juliette seldom talks. Over coffee, Jack talks nonstop. That must be the sort of people they are, we decide. Juliette must be shy and Jack outgoing. Such attributions—to their dispositions—can be valid. People do have enduring personality traits. But sometimes we fall prey to the [fundamental attribution error](#) (Ross, 1977): We overestimate the influence of personality and underestimate the influence of situations. In class, Jack may be as quiet as Juliette. Catch Juliette at a party and you may hardly recognize your quiet classmate.

fundamental attribution error the tendency for observers, when analyzing others' behavior, to underestimate the impact of the situation and to overestimate the impact of personal disposition.

David Napolitan and George Goethals (1979) demonstrated the fundamental attribution error in an experiment with Williams College students. They had students talk, one at a time, with a woman who acted either cold and critical or warm and friendly. Before the conversations, the researchers told half the students that the woman's behavior would be spontaneous. They told the other half the truth—that they had instructed her to *act* friendly (or unfriendly).

Did hearing the truth affect students' impressions of the woman? Not at all! If the woman acted friendly, both groups decided she really was a warm person. If she acted unfriendly, both decided she really was a cold person. They attributed her behavior to her personal disposition *even when told that her behavior was situational*—that she was merely acting that way for the purposes of the experiment.

We all commit the fundamental attribution error. Consider: Is your psychology instructor shy or outgoing?

If you answer “outgoing,” remember that you know your instructor from one situation—the classroom, where teaching demands talking. Your instructor might disagree: “Me, outgoing? It all depends on the situation. In class or with good friends, yes, I’m outgoing. But at professional meetings I’m really rather shy.” Outside their assigned roles, professors seem less professorial, presidents less presidential, managers less managerial.

What Factors Affect Our Attributions?

One factor is culture. Individualist Westerners more often attribute behavior to people's personal traits. People in East Asian cultures are somewhat more sensitive to the power of the situation (Kitayama et al., 2009; Riemer et al., 2014). In experiments that asked people to view scenes, such as a big fish swimming, Americans focused more on the attributes of the individual fish. Japanese viewers focused more on the scene—the situation (Chua et al.,

2005; Nisbett, 2003).

When we explain *our own* behavior, we are sensitive to how behavior changes with the situation (Idson & Mischel, 2001). We also are sensitive to the power of the situation when we explain the behavior of people we have seen in many different contexts. We more often commit the fundamental attribution error when a stranger acts badly. Having only seen that enraged fan screaming at the referee in the heat of competition, we may assume he is a bad person. But outside the stadium, he may be a good neighbor and a great parent.

As we act, our eyes look outward; we see others' faces, not our own. Would taking an observer's viewpoint make us more aware of our own personal style? Researchers tested this idea by using separate cameras to film two people interacting. When they showed each person a replay of the interaction—filmed from the other person's perspective—participants credited their behavior more to their disposition, much as an observer typically would (Lassiter & Irvine, 1986; Storms, 1973).

Two important exceptions to our usual view of our own actions: Our deliberate and *admirable* actions we often attribute to our own good reasons, not to the situation (Malle, 2006; Malle et al., 2007). And as we age, we tend to attribute our younger selves' behavior mostly to our traits (Pronin & Ross, 2006). In five or ten years, your current self may seem like another person.

How Do Our Attributions Matter?

The way we explain others' actions (attributing them to the person or the situation) can have important real-life effects (Fincham & Bradbury, 1993; Fletcher et al., 1990). Does a warm greeting reflect romantic interest or social courtesy? Does a manager's tart-tongued remark reflect a job threat or a bad day? Was a shooting malicious or an act of self-defense? Attributions matter. In one study, 181 state judges gave lighter sentences to a violent offender who a scientist testified had a gene that altered brain areas related to aggressiveness (Aspinwall et al., 2012).

Do you attribute poverty and unemployment to social circumstances or to personal traits? In Britain, India, Australia, and the United States, political conservatives have tended to attribute responsibility to the personal dispositions of the poor and unemployed (Furnham, 1982; Pandey et al.,

1982; Wagstaff, 1982; Zucker & Weiner, 1993). “People generally get what they deserve. Those who take initiative can still get ahead.” In experiments, those who reflect on the power of choice—either by recalling their own choices or taking note of another’s choices—become more likely to think that people get what they deserve (Savani & Rattan, 2012). Political liberals, and those not primed to consider the power of choice, are more likely to blame past and present situations: “If you or I had to live with the same poor education, lack of opportunity, and discrimination, would we be any better off?”

The point to remember: Our attributions—to a person’s disposition or to the situation—have real consequences.

For a quick interactive tutorial, engage online with **Concept Practice: Making Attributions**.

Some 7 in 10 college women report having experienced a man misattributing her friendliness as a sexual come-on (Jacques-Tiura et al., 2007).

“Otis, shout at that man to pull himself together.”

J.B. Handelsman The New Yorker Collection/The Cartoon Bank

Lee Snider/The Image Works

An attribution question

Whether we attribute poverty and homelessness to social circumstances or to personal dispositions affects and reflects our political views.

Richard Ellis/Alamy

Dispositional versus situational attributions

Should the 2015 slaughter of nine African-Americans attending a church Bible study in Charleston, West Virginia, be attributed to the shooter's disposition? ("There is one person to blame here. A person filled with hate," said South Carolina governor Nikki Haley.) Or to America's gun culture? ("At some point, we as a country will have to reckon with the fact that this type of mass violence does not happen in other advanced countries . . . with this kind of frequency," said President Obama.) Or to both?

Attitudes and Actions

LOQ 13-2 How do attitudes and actions interact?

Attitudes are feelings, often influenced by our beliefs, that predispose our reactions to objects, people, and events. If we *believe* someone is threatening us, we may *feel* fear and anger toward the person and *act* defensively. The traffic between our attitudes and our actions is two-way. Our attitudes affect our actions. And our actions affect our attitudes.

attitude feelings, often influenced by our beliefs, that predispose us to respond in a particular way to objects, people, and events.

Attitudes Affect Actions

In any debate, people on both sides attempt to convert the opposition and sway the undecided. These efforts to *persuade* generally take two forms:

- **Peripheral route persuasion** uses attention-getting cues to trigger emotion-based snap judgments. Endorsements by beautiful or famous people can influence people's attitudes, whether the judgment is about choosing a political candidate or buying the latest smart phone. When green activist star Leonardo DiCaprio urges action to counter climate change, or when Pope Francis (2015) states that "Climate change is a global problem with grave implications," they hope to harness their credibility for peripheral route persuasion. Even if it doesn't engage systematic thinking, it may produce fast results.
- **Central route persuasion** offers evidence and arguments that trigger careful thinking. To persuade buyers to purchase a particular phone, an ad might itemize the phone's great features. To marshal support for climate change intervention, effective arguments have focused on accumulating greenhouse gases, melting Arctic ice, rising world temperatures and seas, and extreme weather (van der Linden et al., 2015). Central route persuasion works well for people who are naturally analytical or involved in an issue. And because it is more thoughtful and less superficial, it is more durable.

peripheral route persuasion occurs when people are influenced by incidental cues, such as a speaker's attractiveness.

central route persuasion occurs when interested people focus on the arguments and respond with favorable thoughts.

Persuaders try to influence our behavior by changing our attitudes. But situational factors, such as strong social pressures, can override the attitude-behavior connection (Wallace et al., 2005). In roll-call votes, politicians may vote as their supporters demand, despite privately disagreeing (Nagourney, 2002).

Attitudes are especially likely to affect behavior when external influences are minimal, and when the attitude is stable, specific to the behavior, and easily recalled (Glasman & Albarracín, 2006). One experiment used vivid, easily recalled information to persuade White college student tanners that repetitive tanning put them at risk for future skin cancer. One month later, 72 percent of the participants, and only 16 percent of those in a waitlist control group, had lighter skin (McClendon & Prentice-Dunn, 2001). Persuasion changed attitudes (about skin cancer risk), which changed behavior (less tanning).

Actions Affect Attitudes

Now consider a more surprising principle: Not only will we stand up for what we believe, we also will more strongly believe in what we have stood up for. Many streams of evidence confirm that *attitudes follow behavior* ([FIGURE 13.1](#)).

FIGURE 13.1 Myers/DeWall, *Psychology*, 12e,

Matthias Hangst/Getty Images

FIGURE 13.1 Attitudes follow behavior

Cooperative actions, such as those performed by people on sports teams (including Germany, shown here celebrating their World Cup 2014 victory), feed mutual liking. Such attitudes, in turn, promote positive behavior.

THE FOOT-IN-THE-DOOR PHENOMENON How would you react if someone induced you to act against your beliefs? In many cases, people adjust their attitudes. During the Korean war, many U.S. prisoners were held in Chinese communist war camps. Without using brutality, the captors secured prisoners' collaboration in various activities, ranging from simple tasks (running errands to gain privileges) to more serious actions (false confessions, informing on other prisoners, and divulging military information). When the war ended, 21 prisoners chose to stay with the communists. More returned home “brainwashed”—convinced that communism was a good thing for Asia.

How did the Chinese captors achieve these amazing results? A key ingredient was their use of the [foot-in-the-door phenomenon](#): They knew that people who agree to a small request will find it easier to comply later with a larger one. The Chinese began with harmless requests, such as copying a trivial statement, but gradually escalated their demands (Schein, 1956). The next statement to be copied might list flaws of capitalism. Then, to gain privileges, the prisoners participated in group discussions, wrote self-

criticisms, or uttered public confessions. After doing so, they often adjusted their beliefs to be more consistent with their public acts. The point is simple: To get people to agree to something big, start small and build (Cialdini, 1993). A trivial act makes the next act easier. Succumb to a temptation and you will find the next temptation harder to resist.

foot-in-the-door phenomenon the tendency for people who have first agreed to a small request to comply later with a larger request.

In dozens of experiments, researchers have coaxed people into acting against their attitudes or violating their moral standards, with the same result: Doing becomes believing. After giving in to a request to harm an innocent victim—by making nasty comments or delivering presumed electric shocks—people begin to disparage their victim. After speaking or writing on behalf of a position they have qualms about, they begin to believe their own words.

Fortunately, the attitudes-follow-behavior principle works with good deeds as well. In one classic experiment, researchers sought permission to place a large “Drive Carefully” sign in people’s front yards (Freedman & Fraser, 1966). The 17 percent rate of agreement soared to 76 percent among those who first did a small favor—placing a 3-inch-high “Be a Safe Driver” sign in their window.

The foot-in-the-door tactic has helped boost charitable contributions, blood donations, and U.S. school desegregation. With the passage of the Civil Rights Act of 1964, school desegregation became law. In the years that followed, White Americans expressed diminishing racial prejudice. And as Americans in different regions came to act more alike—thanks to more uniform national standards against discrimination—they began to think more alike.

“If the King destroys a man, that’s proof to the King it must have been a bad man.”

Thomas Cromwell, in Robert Bolt’s *A Man for All Seasons*, 1960

ROLE-PLAYING AFFECTS ATTITUDES When you adopt a new [role](#)—

when you become a college student, marry, or begin a new job—you strive to follow the social prescriptions. At first, your behaviors may feel phony, because you are acting a role. Soldiers may at first feel they are playing war games. Before long, however, what began as play acting in the theater of life becomes *you*. As *Mad Men*'s Bobbie Barrett advised, “Pick a job and then become the person that does it.”

role a set of expectations (norms) about a social position, defining how those in the position ought to behave.

Role playing morphed into real life in one famous and controversial study in which male college students volunteered to spend time in a simulated prison. Stanford psychologist Philip Zimbardo (1972) randomly assigned some volunteers to be guards. He gave them uniforms, clubs, and whistles and instructed them to enforce certain rules. Others became prisoners, locked in barren cells and forced to wear humiliating outfits. For a day or two, the volunteers self-consciously “played” their roles. Then the simulation became real—too real. Some guards developed disparaging attitudes and a third “became tyrannical,” devising cruel and degrading routines. One by one, the prisoners broke down, rebelled, or became passively resigned. After only six days, Zimbardo called off the study.

“Fake it until you make it.”

Alcoholics Anonymous saying

Philip G. Zimbardo; AP Photo

The power of the situation

In his 1972 Stanford Prison simulation, Philip Zimbardo created a toxic situation (left). Those assigned to the guard role soon degraded the prisoners. In real life in 2004, some U.S. military guards tormented Iraqi prisoners at the U.S.-run Abu Ghraib prison (right). To Zimbardo (2004, 2007), it was a bad barrel rather than a few bad apples that led to the Abu Ghraib atrocities: “When ordinary people are put in a novel, evil place, such as most prisons, Situations Win, People Lose.”

To view Philip Zimbardo's 14-minute illustration and explanation of his famous prison simulation, see the **Video—The Stanford Prison Study: The Power of the Situation**.

Critics question the reliability of Zimbardo's results (Griggs, 2014). But this much seems true: Role playing can train people to become torturers in the real world (Staub, 1989). In the early 1970s, the Greek military government eased men into their roles. First, a trainee stood guard outside an interrogation cell. After this “foot in the door” step, he stood guard inside. Only then was he ready to become actively involved in the questioning and torture. In one study of German men, military training toughened their personalities, leaving them less agreeable even five years later, after leaving the military (Jackson et al., 2012). What we do, we gradually become: Every time we act like the people around us, we slightly change ourselves to be more like them, and less like who we used to be.

Yet people differ. In Zimbardo's simulation and in real-life atrocity-producing situations, some people have succumbed to the situation and others have not (Carnahan & McFarland, 2007; Haslam & Reicher, 2007, 2012; Mastroianni & Reed, 2006; Zimbardo, 2007). Person and situation interact.

COGNITIVE DISSONANCE: RELIEF FROM TENSION So far, we have seen that actions can affect attitudes, sometimes turning prisoners into collaborators, doubters into believers, and compliant guards into abusers. But why? One explanation is that when we become aware that our attitudes and actions don't coincide, we experience tension, or *cognitive dissonance*. Indeed, the brain regions that become active when people experience other forms of mental tension and negative arousal also become active when people experience cognitive dissonance (Harmon-Jones et al., 2015; Kitayama et al., 2013). To relieve this tension, according to Leon Festinger's (1957) [cognitive dissonance theory](#), we often bring our attitudes into line with our actions.

cognitive dissonance theory the theory that we act to reduce the discomfort (dissonance) we feel when two of our thoughts (cognitions) are inconsistent. For example, when we become aware that our attitudes and our actions clash, we can reduce the resulting dissonance by changing our attitudes.

To check your understanding of cognitive dissonance, engage online with **Concept Practice: Cognitive Dissonance**.

Dozens of experiments have tested the cognitive dissonance theory. Many have made people feel responsible for behavior that clashed with their attitudes and had foreseeable consequences. As a participant in one of these experiments, you might agree for a measly \$2 to help a researcher by writing an essay supporting something you don't believe in (perhaps a tuition increase). Feeling responsible for the statements (which are inconsistent with your attitudes), you would probably feel dissonance, especially if you thought your essay might influence an administrator. To reduce the uncomfortable tension, you might start believing your phony words. It's as if we rationalize, "If I chose to do it (or say it), I must believe in it." The less coerced and more responsible we feel for a troubling act, the more dissonance we feel. The more dissonance we feel, the more motivated we are to find and project consistency, such as changing our attitudes to help justify the act.

The attitudes-follow-behavior principle has a heartening implication: We cannot directly control all our feelings, but we can influence them by altering our behavior. If we are depressed, we can alter our attributions and explain events in more positive terms, with more self-acceptance and fewer self-put-downs (Rubenstein et al., 2016). If we are unloving, we can become more loving by behaving *as if* we were loving—by doing thoughtful things, expressing affection, giving affirmation. "Each time you ask yourself, 'How should I act?,'" observes Robert Levine (2016), "you are also asking, 'Who is the person I want to become?'" That helps explain why teens' doing volunteer work promotes a compassionate identity. Pretense can become reality. Conduct sculpts character. What we do we become.

The point to remember: We can act ourselves into a way of thinking about as easily as we can think ourselves into a way of acting.

RETRIEVAL PRACTICE

RP-1 Driving to school one snowy day, Marco narrowly misses a car that slides through a red light. “Slow down! What a terrible driver,” he thinks to himself. Moments later, Marco himself slips through an intersection and yelps, “Wow! These roads are awful. The city plows need to get out here.” What social psychology principle has Marco just demonstrated? Explain.

ANSWER: By attributing the other person’s behavior to the person (“he’s a terrible driver”) and his own to the situation (“these roads are awful”), Marco has exhibited the *fundamental attribution error*.

RP-2 How do our attitudes and our actions affect each other?

ANSWER: Our attitudes often influence our actions as we behave in ways consistent with our beliefs. However, our actions also influence our attitudes; we come to believe in what we have done.

RP-3 When people act in a way that is not in keeping with their attitudes, and then change their attitudes to match those actions, _____ theory attempts to explain why.

ANSWER: cognitive dissonance

“Sit all day in a moping posture, sigh, and reply to everything with a dismal voice, and your melancholy lingers. . . . If we wish to conquer undesirable emotional tendencies in ourselves, we must . . . go through the outward movements of those contrary dispositions which we prefer to cultivate.”

William James, *Principles of Psychology*, 1890

Social Influence

Social psychology's great lesson is the enormous power of social influence. This influence stems in part from *social norms*—rules for expected and acceptable behavior. On campus, jeans are the norm; on New York's Wall Street or London's Bond Street, business attire is expected. When we know how to act, how to groom, how to talk, life functions smoothly.

But sometimes social pressure moves people in dreadful directions. Isolated with others who share their grievances, dissenters may gradually become rebels, and rebels may become terrorists. Suicides, bomb threats, airplane hijackings, and mass shootings all have a curious tendency to come in clusters. After a mass killing (of four or more people), the probability of another such attack increases for the ensuing 13 days (Towers et al., 2015). The 100+ U.S. school shootings since 2012 are a modern phenomenon. Let's examine the pull of these social strings. How strong are they? How do they operate? When do we break them?

Conformity: Complying With Social Pressures

LOQ 13-3 What is *social contagion*, and how do conformity experiments reveal the power of social influence?

“Have you ever noticed how one example—good or bad—can prompt others to follow? How one illegally parked car can give permission for others to do likewise? How one racial joke can fuel another?”

Marian Wright Edelman, *The Measure of Our Success*, 1992

Social Contagion

Fish swim in schools. Birds fly in flocks. And humans, too, tend to go with their group, to think what it thinks and do what it does. Behavior is contagious. If one of us yawns, laughs, coughs, scratches, stares at the sky, or

checks our phone, others in our group will often do the same (Holle et al., 2012). Even just reading about yawning increases people's yawning (Provine, 2012), as perhaps you have noticed? Yawn mimicry also occurs in other species—among chimpanzees, for example (Anderson et al., 2004)—and even across species: Dogs more often yawn after observing their owner yawn (Silva et al., 2012).

Tanya Chartrand and John Bargh (1999) call this social contagion the *chameleon effect*, likening it to chameleon lizards' ability to take on the color of their surroundings. They captured it by having students work in a room alongside another person (actually a “confederate” working for the experimenters). Sometimes the confederates rubbed their own face. Sometimes they shook their foot. Sure enough, students tended to rub their face when with the face-rubbing person and shake their foot when with the foot-shaking person.

© Dave Coverly/speedbump.com

“Most people are other people. Their thoughts are someone else's opinions, their lives a mimicry.”

Irish dramatist Oscar Wilde “The Soul of Man Under Socialism,” 1895

“When I see synchrony and mimicry—whether it concerns yawning,

laughing, dancing, or aping—I see social connection and bonding.”

Primatologist Frans de Waal “The Empathy Instinct,” 2009

Social contagion is not confined to behavior. We human chameleons also take on the emotional tones of those around us—their expressions, postures, inflections—and even their grammar (Ireland & Pennebaker, 2010). Just hearing someone reading a neutral text in either a happy- or sad-sounding voice creates *mood contagion* in listeners (Neumann & Strack, 2000).

This natural mimicry enables us to *empathize*—to feel what others are feeling. This helps explain why we feel happier around happy people than around depressed people. It also helps explain why studies of groups of British workers have revealed *mood linkage*, or the sharing of moods (Totterdell et al., 1998). Empathic mimicking fosters fondness (Chartrand & van Baaren, 2009; Lakin et al., 2008). Perhaps you’ve noticed that when someone nods their head as you do and echoes your words, you feel a certain rapport and liking?

Social networks serve as contagious pathways for moods, such as happiness and loneliness, drug use, and even the behavior patterns that lead to obesity and sleep loss (Christakis & Fowler, 2009). On websites, positive ratings generate more positive ratings—a phenomenon called *positive herding* (Muchnik et al., 2013). In a massive experiment on the 2010 U.S. congressional election day, Facebook showed 61 million people a message that encouraged voting, with a link to a local voting place and a clickable “I voted” button. For some recipients, the messages also contained pictures of Facebook friends who had already voted. Those who received “tell your friends you voted” messages were slightly more likely to vote, and that difference generated an estimated 282,000 additional votes.

Suggestibility and mimicry sometimes lead to tragedy. In the eight days following the 1999 shooting rampage at Colorado’s Columbine High School, every U.S. state except Vermont experienced threats of copycat violence. Pennsylvania alone recorded 60 such threats (Cooper, 1999). Spikes in suicide rates sometimes follow a highly publicized suicide (Phillips et al., 1985, 1989). In the wake of screen idol Marilyn Monroe’s suicide on August 5, 1962, the number of suicides in the United States exceeded the usual August count by 200.

Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers

Social contagion

Laughter, like yawns, is infectious. That's what "Chewbacca Mom's" (Candace Payne's) viewers discovered after her spontaneous hilarity became, with 164 million views, Facebook Live's most watched 2016 video (tinyurl.com/ThatLaugh).

What causes behavior clusters? Do people act similarly because of their influence on one another? Or because they are simultaneously exposed to the same events and conditions? Seeking answers to such questions, social psychologists have conducted experiments on conformity.

Reprinted by permission of Universal Press Syndicate. © 1997 Wiley.

Conformity and Social Norms

Suggestibility and mimicry are subtle types of **conformity**—adjusting our

behavior or thinking toward some group standard. To study conformity, Solomon Asch (1955) devised a simple test. Imagine yourself as a participant in a supposed study of visual perception. You arrive in time to take a seat at a table with five other people. The experimenter asks the group to state, one by one, which of three comparison lines is identical to a standard line. You see clearly that the answer is Line 2, and you wait your turn to say so. Your boredom begins to show when the next set of lines proves equally easy.

conformity adjusting our behavior or thinking to coincide with a group standard.

Now comes the third trial, and the correct answer seems just as clear-cut ([FIGURE 13.2](#)). But the first person gives what strikes you as a wrong answer: “Line 3.” When the second person and then the third and fourth give the same wrong answer, you sit up straight and squint. When the fifth person agrees with the first four, you feel your heart begin to pound. The experimenter then looks to you for your answer. Torn between the unanimity voiced by the five others and the evidence of your own eyes, you feel tense and suddenly unsure. You hesitate before answering, wondering whether you should suffer the discomfort of being the oddball. What answer do you give?

FIGURE 13.2 Myers/DeWall, *Psychology*, 12e, © 2018 Worth Publishers
William Vandivert/Scientific American

FIGURE 13.2 Asch's conformity experiments

Which of the three comparison lines is equal to the standard line? What do you suppose most people would say after hearing five others say, “Line 3”? In this photo from one of Asch's experiments, the student in the center shows the severe discomfort that comes from disagreeing with the responses of other group members (in this case, accomplices of the experimenter).

In Asch's experiments, college students, answering questions alone, erred

less than 1 percent of the time. But what happened when several others—confederates—answered incorrectly? Although most people told the truth even when others did not, Asch was disturbed by his result: More than one-third of the time, these “intelligent and well-meaning” college students were “willing to call white black” by going along with the group.

SanneBerg/Getty Images

Tattoos: Yesterday's nonconformity, today's conformity?

As tattoos become perceived as fashion conformity, their popularity may wane.

Later investigations have not always found as much conformity as Asch found, but they have revealed that we are more likely to conform when we

- are made to feel incompetent or insecure.
- are in a group with at least three people.
- are in a group in which everyone else agrees. (If just one other person disagrees, the odds of our disagreeing greatly increase.)
- admire the group's status and attractiveness.

- have not made a prior commitment to any response.
- know that others in the group will observe our behavior.
- are from a culture that strongly encourages respect for social standards.

Why do we so often think as others think and do as they do? Why, when asked controversial questions, are students' answers more similar when they raise their hands and more diverse when they use anonymous electronic clickers (Stowell et al., 2010)? Why do we clap when others clap, eat as others eat, believe what others believe, say what others say, even see what others see?

Frequently, we conform to avoid rejection or to gain social approval (Williams & Sommer, 1997). In such cases, we are responding to **normative social influence**. We are sensitive to social norms because the price we pay for being different can be severe. We need to belong. At other times, we conform because we want to be accurate. Groups provide information, and only an uncommonly stubborn person will never listen to others. When we accept others' opinions about reality, as when reading online movie and restaurant reviews, we are responding to **informational social influence**. As one female Welsh driver demonstrated in 2004, sometimes it pays to assume others are right and to follow their lead. She set a record for the longest distance driven on the wrong side of a British divided highway—30 miles, with only one minor sideswipe, before the motorway ran out and police were able to puncture her tires. The driver, who was intoxicated, later explained that she thought the hundreds of other drivers coming at her were all on the wrong side of the road (Woolcock, 2004).

normative social influence influence resulting from a person's desire to gain approval or avoid disapproval.

informational social influence influence resulting from one's willingness to accept others' opinions about reality.

Is conformity bad or good? Conformity can be bad—leading people to agree with falsehoods or go along with bullying. Or it can be good—leading people to give more generously after observing others' generosity (Nook et

al., 2016). The answer also depends partly on our culturally influenced values. People in many Asian, African, and Latin American countries place a high value on *collectivism* (honoring group standards). Western Europeans and people in most English-speaking countries tend to prize *individualism* (giving priority to personal goals over group goals). Experiments across 17 countries have found lower conformity rates in individualist cultures (Bond & Smith, 1996). American university students, for example, tend to see themselves as less conforming than others (Pronin et al., 2007). We are, in our own eyes, individuals amid a crowd of sheep.

RP-4 Despite her mother's pleas to use a more ergonomic backpack, Antonia insists on trying to carry all of her books to high school in an oversized purse the way her fashionable friends all seem to do. Antonia is affected by what type of social influence?

ANSWER: Normative social influence

Obedience: Following Orders

LOQ 13-4 What did Milgram's obedience experiments teach us about the power of social influence?

Social psychologist Stanley Milgram (1963, 1974), a high school classmate of Philip Zimbardo and then a student of Solomon Asch, knew that people often give in to social pressures. But how would they respond to outright commands, as did those who carried out Holocaust atrocities? (Some of Milgram's family members were Nazi concentration camp survivors.) To find out, he undertook what have become social psychology's most famous and controversial experiments (Benjamin & Simpson, 2009).

Imagine yourself as one of the nearly 1000 people who took part in Milgram's 20 experiments. You respond to an ad for participants in a Yale University psychology study of the effect of punishment on learning. Professor Milgram's assistant asks you and another person to draw slips from a hat to see who will be the "teacher" and who will be the "learner." You draw a "teacher" slip (unknown to you, both slips say "teacher"). The supposed learner, a mild and submissive-seeming man, is led to an adjoining room and strapped into a chair. From the chair, wires run through the wall to your machine. You sit down in front of a shock machine and are given your task: Teach and then test the learner on a list of word pairs. If the learner gives a wrong answer, you are to flip a switch to deliver a brief electric shock. For the first wrong answer, you will flip the switch labeled "15 Volts—Slight Shock." With each succeeding error, you will move to the next higher voltage. With each flip of a switch, lights flash and electronic switches buzz.

The experiment begins, and you deliver the shocks after the first and second wrong answers. If you continue, you hear the learner grunt when you flick the third, fourth, and fifth switches. After you activate the eighth switch ("120 Volts—Moderate Shock"), the learner cries out that the shocks are painful. After the tenth switch ("150 Volts—Strong Shock"), he begins shouting. "Get me out of here! I won't be in the experiment anymore! I refuse to go on!" You draw back, but the stern experimenter prods you: "Please continue—the experiment requires that you continue." You resist, but the experimenter insists, "It is absolutely essential that you continue," or "You have no other choice, you *must* go on."

If you obey, you hear the learner shriek in apparent agony as you continue to raise the shock level after each new error. After the 330-volt level, the learner refuses to answer and falls silent. Still, the experimenter pushes you toward the final, 450-volt switch. "Ask the question," he says, "and if no correct answer is given, administer the next shock level."

Like humans, migrating and herding animals conform for both informational and normative reasons (Claidière & Whiten, 2012). Following others is informative; compared with solo geese, a flock of geese migrate more accurately. (There is wisdom in the crowd.) And staying with the herd also sustains group membership.

Would you follow the experimenter's commands to shock someone? At what level would you refuse to obey? Before undertaking the experiments, Milgram asked nonparticipants what they would do. Most were sure they would stop soon after the learner first indicated pain, certainly before he shrieked in agony. Forty psychiatrists agreed with that prediction. Were the predictions accurate? Not even close. When Milgram conducted the experiment with other men aged 20 to 50, he was astonished. More than 60 percent complied fully—right up to the last switch. When he ran a new study, with 40 new “teachers” and a learner who complained of a “slight heart condition,” the results were similar. A full 65 percent of the new teachers obeyed the experimenter, right up to 450 volts ([FIGURE 13.3](#)). In 10 later studies, women obeyed at rates similar to men's (Blass, 1999).

FIGURE 13.3 Milgram's follow-up obedience experiment

In a repeat of the earlier experiment, 65 percent of the adult male “teachers” fully obeyed the experimenter's commands to continue. They did so despite the “learner's” earlier mention of a heart condition and despite hearing cries of protest after they administered what they thought were 150 volts and agonized protests after 330 volts.

Were Milgram's results a product of the 1960s American mindset? No. When Jerry Burger (2009) substantially repeated Milgram's basic

experiment, 70 percent of the participants complied up to the 150-volt point—only a slight reduction from Milgram’s 83 percent. And when a French reality TV show replicated Milgram’s study, 81 percent of the teachers, egged on by a cheering audience, obeyed and tortured a screaming victim (Beauvois et al., 2012).

Did Milgram’s teachers figure out the hoax—that no real shock was being delivered and the learner was in fact a confederate pretending to feel pain? Did they realize the experiment was really testing their willingness to comply with commands to inflict punishment? No. The teachers typically displayed genuine distress: They perspired, trembled, laughed nervously, and bit their lips.
